C, Just above the ventricle (level of the false cord). The paraglottic space is filled with fat (arrow). The upper arytenoid cartilage (A) is visible.

D, True cord level. The thyroarytenoid muscle (TAM) fills the paraglottic space. The cricoarytenoid joint is shown by an arrowhead. The upper margin of the cricoid cartilage is visible.

E, Subglottis. The mucosa is tightly applied to the inner surface of the cricoid ring (C) without intervening soft tissue.

At our institution, before the examination begins, usually before the patient is placed on the table, the patient practices breathing with the abdominal muscles rather than with the chest muscles. Surface coils, a necessity in laryngeal MRI studies, are positioned so that any chest movement does not bump the coil. Although speed of imaging is always an advantage, some have recommended using up to multiple excitations on the T1-weighted sequence. This gives longer imaging times but averages out some of the

motion. Fast spin-echo imaging also shortens imaging times.

The use of contrast agents is controversial. At our institution, contrast material is usually used for tumor imaging. Gadolinium, combined with fat suppression, has given good preliminary results.

Imaging emphasizes the importance of the ventricle, and axial images are taken along the plane of the ventricle. The position of the ventricle is estimated in axial images by the

Figure 18-6. Reformatted coronal image through the larynx (multidetector CT). The patient is holding his breath. The position of the closed airway is represented by the *dashed line*. Note the density of fat in the paraglottic space at the supraglottic level (*arrow*). The thyroarytenoid muscle (*arrowhead*) forms the bulk of the true cord (glottic level). The thyroid cartilage and cricoid cartilage are also visible. H, hyoid bone; T, thyroid gland.

appearance of the cartilages or by the transition from the fat to muscle in the paraglottic region.

In MRI studies, the coronal images are perpendicular to the ventricle. Even if the ventricle is not actually visible, its position can be predicted by the transition from fat to muscle in the paraglottic space.

Pathology

Most laryngeal imaging is performed in order to evaluate patients with tumors of or trauma to the larynx.^{11-14, 21, 23, 24} The tumors can be mucosal or submucosal. In most instances, the larynx is visualized directly—if not by endoscopy, at least by mirror—and the radiologist should emphasize information that is not obtainable by direct visualization.

Mucosal Tumors

Most tumors that come to imaging are squamous cell carcinomas arising from the mucosa of the larynx.² With the possible exception of rare tumors arising deep within the ventricle, these tumors are detected before imaging. Indeed, imaging currently cannot rule out a small malignancy and thus is not a substitute for direct visualization.

The otolaryngologist can assess smaller lesions completely. The margins of a small tumor may be readily visible, with no further information required. Alternatively, a patient with a large tumor may obviously require a total laryngectomy, and imaging may not add significant information. Imaging is most important for the patients with moderate-sized tumors in whom some sort of voice-sparing procedure is considered. Such treatment options include partial laryngectomies and radiotherapy. The feasi-

bility of these therapies depends on the origin and the extent of the tumor. The following discussion of imaging of carcinoma of the larynx is organized according to the tumor's site of origin.

Supraglottic Tumors

The usual voice-sparing surgical option for supraglottic squamous cell carcinoma is the supraglottic laryngectomy (Fig. 18-7). The resection is made along the ventricle, and the surgeon removes the entire supraglottic larynx, leaving at least one—and usually both—arytenoid cartilages.^{1, 10, 18, 26} The patient retains the true cords and can thus generate voice in the usual manner. The protective function of the supraglottic larynx, particularly the epiglottis, is lost, and the patient must learn how to swallow without aspirating.

Tumor crossing the ventricle is the primary contraindication for the supraglottic laryngectomy (Box 18-1). The incision passing along the ventricle would cut through tumor. Tumor growing along the mucosa to reach the true cord may be obvious at direct visualization. In a smaller lesion, the tumor may invade into the deeper tissues and follow the paraglottic space around the ventricle into the lateral edge of the true cord. This type of spread is unusual

Figure 18-7. Diagram of a supraglottic laryngectomy. The *dotted line* shows the incision of a supraglottic laryngectomy and passes along the ventricle between the true cord and the false cord (2). AE, aryepiglottic fold; C, cricoid cartilage; E, epiglottis; T, thyroid cartilage. (From Curtin HD: Imaging of the larynx: Current concepts. Radiology 173:1-11, 1989.)

as an isolated phenomenon but should be checked during imaging of a supraglottic tumor.

Box 18-1. Contraindications to Supraglottic Laryngectomy

- Tumor extension onto the cricoid cartilage
- Bilateral arytenoid involvement
Arytenoid fixation
- Extension onto the glottis or impaired vocal cord mobility
- Thyroid cartilage invasion
- Involvement of the apex of the piriform sinus or post-cricoid region
- Involvement of the base of the tongue more than 1 cm posteriorly to the circumvallate papillae

From Lawson W, Biller HF, Suen JY: Cancer of the larynx. In Suen JY, Myers E (eds): Cancer of the Head and Neck. New York, Churchill Livingstone, 1989, pp 533-591.

Axial imaging parallels the ventricle and, therefore, is somewhat limited in its ability to identify the level of this key structure. The paraglottic space of the false cord level is predominantly fat, but at the true cord level it is predominantly muscle. The transition between the two represents the approximate level of the ventricle.

If a normal slice can be found below the tumor but still within the supraglottic larynx, the supraglottic laryngectomy is technically possible (Fig. 18-8). If the tumor can be identified at the level of the cord as well as in the supraglottis, the decision is again made and the patient cannot have the usual supraglottic resection. If surgery is chosen as the therapy, the patient must have a total laryngectomy.

On axial images, the lateral edge of the TAM should be carefully examined for the earliest evidence of transglottic spread. A narrow extension of the paraglottic fat is often seen along the outer margin of the muscle. Tumor spreading around the ventricle will grow into this fat and eventu-

Figure 18-8. CT scan of a supraglottic tumor separated from the ventricle. **A**, Axial slice shows the tumor (T) at the level of the hyoid bone. Note the metastatic nodes (N). The left node shows considerable irregularity, indicating extracapsular tumor spread. **B**, The axial slice, slightly lower than in **A**, is normal. The normal paraglottic fat (arrowhead) indicates that the slice is at the supraglottic level and thus between the tumor and the ventricle. **C**, A slice through the true vocal cord would show the normal muscle density (arrowhead). The vocal process is represented by an arrow.

Figure 18-9. Supraglottic tumor with paraglottic spread into the lateral edge of the true cord. *A*, Axial slice through the supraglottic level shows the tumor (T). Note the interface of tumor with fat in the preepiglottic space (arrowhead) and the normal paraglottic fat (arrow) on the opposite side. *B*, Axial slice at the level of the cord shows a small amount of tumor (arrow) prying its way between the thyroid cartilage (T) and the thyroarytenoid muscle (TAM) (open arrow). This is at the true cord level below the level of the ventricle. A, arytenoid. (B, From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

ally will appear to “pry” the muscle away from the thyroid cartilage.

Tumor can be distinguished readily from the fat in the supraglottic paraglottic space. The interface between tumor and muscle at the true cord level is more difficult to visualize. MRI offers the advantage of better tissue differentiation because of its various pulse sequences, but this advantage can be realized only if the patient is able to control motion (Fig. 18-9).

Coronal images are perpendicular to the ventricle and may also be helpful in showing the relationship between tumor and the lateral aspect of the true cord (Figs. 18-10 and 18-11).

Midline tumor can cross the level of the ventricle to involve the anterior commissure. This area can be difficult to evaluate either by direct visualization or by imaging. If there is deep growth from the anterior commissure into the attachment of the cord or through the cricothyroid membrane, imaging may detect tumor that is unappreciated clinically (see “True Cord”).

Anterior growth from a supraglottic carcinoma brings the tumor into the preepiglottic space (see Figs. 18-8 and 18-9). The preepiglottic space as well as the paraglottic space has a rich lymphatic drainage, and tumor invasion heightens the concern regarding nodal metastases. Invasion is easily appreciated on axial imaging because the tumor is contrasted against the fat. Such involvement is not a contraindication to a supraglottic laryngectomy.

Thyroid cartilage invasion is usually considered a contraindication to the supraglottic laryngectomy. Such invasion is uncommon unless the tumor is large and has crossed the ventricle.¹⁶ In such a case, the patient would be excluded as a candidate on the basis of ventricular involvement. Involvement of the epiglottic cartilage is not a contraindication. (Cartilage assessment is discussed in the text on true cord lesions.)

The supraglottic partial laryngectomy is the most accepted surgical therapy for tumors limited to the area above the ventricle. More extensive resections have been used for lesions extending beyond the boundaries of supraglottic laryngectomy.¹⁹ Pearson’s near-total laryngectomy is done for supraglottic cancer extending to one cord. The resection

Figure 18-10. Supraglottic carcinoma extending around the ventricle into the lateral cord. The tumor (T) is readily visible to the endoscopist. A small amount of tumor (arrow) is seen extending around the lateral aspect of the ventricle into the superolateral margin of the thyroarytenoid muscle (TAM). The mucosa at the true cord level was normal. Thyroid cartilage is represented by a white arrow. (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

Figure 18-11. Transglottic tumor, reformatted coronal image (multidetector). *A*, The tumor follows (arrow) the paraglottic space around the ventricle widening the cord as the tumor infiltrates. An arrowhead represents the approximate level of the ventricle. *B*, Note the relationship of the tumor to the arytenoid cartilage (arrow), the thyroid cartilage (T) (immediately lateral), and the cricoid (C). N, metastatic node.

is continued to include the cord and to take the upper margin of the cricoid. The supracricoid partial laryngectomy with cricohyoidopexy takes the anterior cords to the level of cricoid. Minor involvement of the thyroid cartilage is not a contraindication. In either of these approaches, the inferior extent remains the most important assessment at imaging.

An alternative to the partial laryngectomies already mentioned is endoscopic laser surgery.²⁶ Lesions of the suprahoid epiglottis, the AE fold, and the false cord are more appropriate for this type of surgery compared with lesions of the laryngeal surface of the epiglottis. The latter tumors are partially hidden by the epiglottis and thus are less accessible to endoscopic resection.

Radiation therapy is also performed for supraglottic cancer. The same landmarks and considerations for supraglottic laryngectomy pertain to assessment for radiation therapy. The bulk of the tumor is also a prognostic factor. Patients with larger tumors fare worse than those with smaller tumors. One study used a 6-mL volume as a separation, with larger tumors carrying a much worse prognosis than smaller ones.²⁰

Nodal metastases are very common in supraglottic tumors. Metastases can be bilateral.

True Cord

There are several options for therapy of glottic carcinoma, including simple resection, laser resection, and radiotherapy. Vertical hemilaryngectomy may be considered for a lesion involving the true cord. In this procedure, the surgeon removes the true and false cord on one side of the larynx using a vertical incision through the thyroid cartilage.

The lesion can cross the anterior commissure and involve the anterior one third of the opposite cord and still be treatable by vertical hemilaryngectomy. The incision through the thyroid cartilage is moved laterally toward the opposite side.

Contraindications for vertical hemilaryngectomy are listed in Box 18-2. The most important assessments done at imaging concern inferior extension of the tumor, deep invasion at the anterior commissure, and cartilage invasion. Submucosal superior extension crossing the ventricle into the supraglottic larynx is a problem only occasionally.

Box 18-2. Contraindications to Vertical Frontolateral Hemilaryngectomy*

- Tumor extension from the ipsilateral vocal cord across the anterior commissure to involve more than one third of the contralateral vocal cord
- Extension subglottically >10 mm anteriorly and >5 mm posterolaterally
- Extension across the ventricle to the false cord
- Thyroid cartilage invasion
- Impaired vocal cord mobility a relative contraindication

*This technique can still be used if the vocal process and anterior surface of the arytenoid are involved, but involvement of the cricoarytenoid joint, interarytenoid area, opposite arytenoid, or rostrum of the cricoid is a contraindication.

From Lawson W, Biller HF, Suen JY: Cancer of the larynx. In Suen JY, Myers E (eds): Cancer of the Head and Neck. New York, Churchill Livingstone, 1989, pp 533-591.

Inferior extension is quantified relative to the cricoid cartilage. The cricoid cartilage is the foundation of the

Figure 18-12. Vocal cord lesion with subglottic extension. T1-weighted MRI study. The patient presented with a lesion of the true cord (not shown). The tumor (T) is within the ring of the cricoid cartilage (C). Note the intact fat planes (*arrowheads*) just anterior to the cricothyroid membrane. SCM, sternocleidomastoid. (From Curtin HD: *Imaging of the larynx: Current concepts*. Radiology 173:1-11, 1989.)

larynx, and most surgeons suggest that even partial resections of this important cartilage are not possible.

At imaging, if the tumor can be identified within the ring of the cricoid cartilage, the standard vertical laryngectomy cannot be done and laryngectomy is usually recommended (Fig. 18-12).

Deep invasion at the anterior commissure may involve the thyroid cartilage or the cricothyroid membrane (Fig. 18-13; see Fig. 18-12).¹⁷ The subtle fat plane anterior to

Figure 18-13. Tumor of the anterior commissure extending anteriorly. A small tumor was seen at the anterior commissure (*white arrow*). Anterior extension carried the tumor through the thyroid cartilage (*arrowheads*) with a prominent nodule in the anterior soft tissues (*black arrow*). N, metastatic node. (From Curtin HD: *The larynx*. In Som PM, Bergeron RT [eds]: *Head and Neck Imaging*, 2nd ed. St. Louis, Mosby-Year Book, 1991.)

the membrane should be examined closely on the axial image.

Cartilage invasion (discussed next) is considered a contraindication for vertical hemilaryngectomy. Minor thyroid cartilage invasion has been treated with supracricoid partial laryngectomy with cricohyoepiglottopexy.¹⁹ In this procedure, more of the supraglottic larynx is removed and the cricoid cartilage is then suspended from the remaining supraglottic tissues and hyoid bone.

Cartilage Invasion

Cartilage invasion is considered a contraindication to both the standard supraglottic and vertical hemilaryngectomies. The subject is discussed here because such invasion is more of a concern in lesions involving the true cord.

With both CT and MRI studies, the most reliable sign of cartilage involvement is identification of tumor on the extralaryngeal or outer surface of the cartilage. Minor degrees of cartilage invasion can be difficult to detect. The variability of ossification of the major cartilages can lead to problems in detecting cartilage invasion.

The nonossified part of the cartilage can have approximately the same appearance as tumor on CT scans. MRI has the advantage of better tissue discrimination, and although there are no large series available, early results suggest that tumor can be differentiated from nonossified cartilage based on the intensity of the signal.^{7,8}

If signal is bright on the T1-weighted image, that part of the cartilage can reliably be considered normal. The high signal represents fat in ossified cartilage, and carcinoma is never that bright. On T1-weighted images, tumor and nonossified cartilage are usually dark. The nonossified cartilage may be slightly darker than tumor. Regions that are dark on T1-weighted images are examined on the long repetition time (TR) sequence. Nonossified cartilage remains relatively dark on long TR sequence images. Tumor tends to be significantly brighter than nonossified cartilage (Figs. 18-14 and 18-15). One cannot rely on the long TR image alone because fat may be fairly bright, even though the sequence is T2-weighted. Indeed, the tumor may have the same signal as the fat on T2-weighted images particularly if fast spin-echo sequences are used.

Tumor, then, is dark or intermediate on T1-weighted images and usually relatively brighter on T2-weighted images. T2-weighted images show tumor as intermediate to bright. This signal pattern does not definitely indicate tumor. Edema, fibrosis, or even red marrow have also been described with this pattern.⁴

Edema is of particular concern because squamous cell carcinoma often has a peritumoral inflammatory response. Edema may be slightly brighter than tumor on T2-weighted images, but more experience is needed before a definite statement can be made regarding separation of tumor and edema. Edema of the cartilage presumably means that tumor is at least very close. In my experience, at least the perichondrium has been invaded if edema is present in the cartilage.

At CT, irregularity of the inner cortex may suggest that tumor is eroding; however, this sign is questionable because of the variability of ossification. The cortex may be interrupted normally. Asymmetric sclerosis, particularly of

Figure 18-14. Supraglottic tumor without cartilage invasion. *A*, Short TR, short TE. The tumor (arrow) abuts an area of the cartilage (arrowhead) that has the same signal intensity. On the opposite side, a normal ossified thyroid lamina with bright signal of medullary fat (open arrow) is identified. *B*, Long TR, short TE. The tumor (arrow) is significantly brighter than the nonossified cartilage (arrowhead). (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

the thyroid and cricoid cartilages, may indicate tumor.⁴ Tumor may obliterate the medullary fat within the cartilage.

Further study regarding the significance of various signal patterns and CT findings is needed. For instance, the effect of the various imaging findings on prognosis of various therapies, particularly radiotherapy, may potentially change management.⁹

Subglottic Tumors

Subglottic tumors are rare. When they do occur, the only surgical option is almost always a total laryngectomy because of the proximity to the cricoid cartilage.

Hypopharynx

Although the hypopharynx is not actually part of the larynx, it is so intimately associated that discussion is warranted here. Decisions about potential surgical resection usually relate to the proximity of the tumor to landmarks within the larynx, and the assessment is thus quite similar to that of lesions within the larynx itself.

Two regions of the hypopharynx have important relationships to the larynx: the *piriform sinuses* and the *postcricoid region*.

The piriform sinuses indent the posterior wall of the

Figure 18-15. Tumor involving cartilage, axial MRI study. *A*, Short TR, short TE T1-weighted image shows tumor (T) against a suspicious area of cartilage (small arrowheads). The cartilage has a more intermediate signal rather than the high signal of fat. A normal thyroid lamina is seen on the opposite side (open arrow). *B*, Long TR, long TE T2-weighted image shows significant "brightening" compared with that in *A*. The behavior of this area is the same as that of the tumor. Nonossified cartilage remains as a dark linear structure within the higher-intensity tumor. (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

Figure 18–16. Tumor (T) of the piriform sinus. The lesion protrudes through the thyroarytenoid gap between thyroid cartilage and arytenoid (arrow). The tumor thus invades the paraglottic space (arrowhead) of the supraglottic larynx. Compare with the fat in the paraglottic space on the normal side. C, carotid artery.

larynx. The anterior wall of the piriform sinuses represents the posterior wall of the paraglottic space. The piriform sinus makes up the lateral aspect of the AE fold.

If a tumor is localized to the upper piriform sinus, a supraglottic resection may be considered along with resection of the tumor. A tumor that invades the paraglottic region of the larynx can follow the paraglottic pathway to reach the level of the cord, and in these patients a total laryngectomy is usually required (Fig. 18–16).

The postcricoid region is that area of the lower hypopharynx that covers the posterior aspect of the cricoid cartilage. To achieve an appropriate margin, the surgeon must usually remove the cricoid and then perform a total laryngectomy. In these patients, the inferior extension within the pharynx should be estimated to help the surgeon decide the appropriate method of reconstructing the food passage.

Lymph Nodes

Metastasis to the lymph nodes is a major consideration in carcinoma of the larynx. The subject of lymph nodes is covered elsewhere in this book, but brief comments about major pathways of spread are appropriate.

Nodal metastases are a major concern with supraglottic tumors. Spread to the jugular nodes occurs very frequently because of the rich lymphatic drainage. The margin of the true cord does not have any lymphatics; therefore, tumors of the true cord do not spread to the lymph nodes unless there is deep invasion or, alternatively, unless the tumor has grown along the mucosa to involve the subglottic region.

Because the subglottic mucosa does have lymphatic drainage, a primary tumor arising in this location or a glottic tumor extending into the area secondarily can metastasize to the nodes. In these patients, the nodes along

the esophagus and in the upper mediastinum become a significant concern.

Radiation Therapy

From a surgical perspective, the evaluation of patients uses landmarks that are slightly more precise, but many of the same findings are appropriate when radiotherapy is chosen as the treatment.

The dimensions of the tumor in the axial plane are relevant, since they reflect the bulk of the tumor and relate to the depth of invasion into the soft tissues.

The vertical extent of the tumor should be estimated, although the precision relating to the ventricle is less crucial. Extension into the subglottic area is very important because the treatment portals may be changed to include the paratracheal and upper mediastinum regions.

Formerly, cartilage involvement was considered a contraindication to radiation therapy. Tumor recurrence is more frequent, as is radiation chondritis and chondronecrosis. More recently, however, some have expressed the opinion that relatively subtle involvement is not an absolute contraindication.

Other Mucosal Tumors

Many benign lesions, such as polyps and papillomas, arise from the mucosa of the larynx. These lesions are seldom evaluated by CT or MRI studies. Submucosal tumors can ulcerate through the mucosa (see “Submucosal Tumors” next).

Although almost all malignancies arising from the mucosa of the larynx are squamous cell carcinoma, occasional malignancies arise from the minor salivary glands with histologies such as adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma.

Verrucous carcinoma is an exophytic, slow-growing variant of squamous cell carcinoma. It does not usually metastasize, but it can be locally aggressive. There are no particular imaging features, but the lesion has a typical exophytic “warty” appearance on direct inspection.

Submucosal Tumors

Lesions presenting beneath an intact mucosa usually arise from the nonepithelial elements of the larynx.^{2,3} Such tumors include chondroid lesions, hemangiomas, neurogenic tumors, and rare lesions such as leiomyoma, rhabdomyoma, and lipomas. Sarcomas arising from the same various mesenchymal elements are often submucosal, but with increasing size they can lead to mucosal ulceration.

In rare instances, a squamous cell carcinoma can appear to be entirely submucosal. Such a lesion arises in the ventricle or ventricular saccule (appendix). The tumor expands upward into the paraglottic space and downward into the true cord rather than medially toward the lumen of the larynx.

A submucosal tumor represents a different problem. Unlike the squamous cell carcinoma, in which the actual tumor can be seen and is easily accessible for biopsy, the submucosal tumor presents as a bulge beneath an intact mucosa. In these patients, imaging is used not only to show

Figure 18-17. Chondroid lesion of the cricoid cartilage. The lesion (arrow) expands the cricoid cartilage. The apparent origin in the cartilage suggests the diagnosis. A higher slice showed calcifications.

the extent of the lesion but also to help identify the type of tumor. With certain tumors, the findings are characteristic enough that the diagnosis can be predicted accurately. When the diagnosis is not definitive after imaging, certain findings can still be helpful to the otolaryngologist.

The first question is whether the tumor is a chondroid lesion. Chondrosarcomas and chondromas arise from the cartilaginous framework of the larynx (Figs. 18-17 and 18-18); most arise from the cricoid. The thyroid cartilage is the second most common site of origin. Differentiation

between benign and malignant can be difficult even at histopathologic examination. These tumors can compromise the airway, and treatment is usually surgical. A partial laryngectomy can be curative if the entire lesion is resected. If the cricoid cartilage is extensively involved, a total laryngectomy may be considered because of the key role of this cartilage in maintaining a patent airway.

With either CT or MRI, the cricoid origin may be obvious and may give a clue as to the identity of the lesion (see Fig. 18-17). The cartilage may be expanded, indicating a lesion arising within the cricoid rather than eroding into the cartilage from a more superficial mucosal origin.

The cartilaginous matrix is the most characteristic finding at imaging (see Fig. 18-18). CT scans are better than MRI studies at demonstrating the calcifications within the matrix of the tumor. Such calcifications are extremely rare in other lesions. Relapsing polychondritis can have fairly extensive calcification; however, this is extremely rare and should not involve the larynx exclusively.

If the lesion does not have the imaging characteristics of a cartilage lesion, the radiologist tries to determine whether the lesion is vascular. Hemangiomas and paragangliomas enhance intensely on CT scans if a bolus or rapid drip of intravenous contrast material is used. The knowledge that a tumor is vascular has obvious implications if biopsy or resection is planned.

Most of the other tumors mentioned have no specific identifying characteristics. They do not have a cartilaginous matrix and do not enhance brightly. The absence of these two imaging characteristics is useful information in limiting the diagnostic possibilities.

Cysts also present as submucosal masses and are described next.

Cysts

Three types of cysts arise within or in intimate association with the larynx: The *saccular* cyst (laryngocele) and the *mucosal* cyst arise within the larynx, and the *thyroglos-*

Figure 18-18. Chondrosarcoma, axial CT scan. A, The tumor expands (arrowhead) the thyroid lamina. B, Note the stippled density (arrow) within the cartilage representing cartilage formation.

Figure 18-19. Diagram of a laryngocele. Coronal section through the larynx shows the ventricle (arrow) and the ventricular appendix (arrowhead) on the normal side. When this appendix is obstructed, it dilates (i.e., it fills with either fluid or air) to form a saccular cyst or laryngocele. In the diagram, the lateral extent of the saccular cyst protrudes through the lateral cricothyroid membrane. (From Curtin HD: The larynx. In Som PM, Bergeron RT [eds]: Head and Neck Imaging, 2nd ed. St. Louis, Mosby-Year Book, 1991.)

sal duct cyst arises just outside the larynx in close association with the strap muscles.

Saccular Cyst (Laryngocele)

The saccular cyst, or laryngocele, represents a dilatation of the ventricular saccule or appendix (Fig. 18-19). Strict terminology refers to the abnormality as a saccular cyst if it is fluid-filled and as a laryngocele if it is air-filled. Many simply refer to the lesions as air-filled or fluid-filled laryngoceles. The laryngocele is a supraglottic abnormality, and the true cord is normal.

Either presents as a submucosal mass or bulge in the supraglottic larynx (Figs. 18-20 to 18-22). The air or fluid within is readily identifiable, and the extent can be determined. A small cyst or laryngocele may be confined to the supraglottic paraglottic space and is referred to as "internal." A larger lesion may protrude laterally through the thyrohyoid membrane just anterior to the upper horn of the thyroid cartilage. Any component outside the membrane is referred to as "external" (see Fig. 18-21). A pure external laryngocele is rare. The external component is seen in combination with an internal component. This is called a *mixed laryngocele*. When the external component is large, the laryngocele can present as a neck mass.

Laryngoceles and saccular cysts are benign. However, these abnormalities can occur when tumor in the ventricle causes obstruction of the laryngeal saccule; therefore, both the radiologist and the endoscopist must carefully examine this key area (see Fig. 18-22).

Mucosal Cyst

A mucosal cyst is considered to be an obstructed mucous gland and can present anywhere mucosa is present. The benign nature of this cyst may be suggested by the smooth appearance, and this diagnosis is considered when a cystic-appearing mass is found on a mucosal surface.

Thyroglossal Duct Cyst

The thyroglossal duct cyst arises from the remnant left as the thyroid gland descends to the appropriate position in the lower neck. The cyst can arise above or below the hyoid bone. A cyst that arises below the hyoid bone is usually found just off midline in the region of the strap muscles anterior to the larynx (Fig. 18-23).

The appearance of the thyroglossal duct cyst is characteristic and should not be confused with saccular cyst arising within the larynx itself. A thyroglossal duct cyst in rare circumstances may bulge over the anterior notch of the thyroid cartilage but should not pass through the lateral aspect of the thyrohyoid membrane. The paraglottic space should not be involved.

Post-therapy Appearance of the Larynx

Both surgery and radiotherapy significantly distort the normal appearance of the larynx.

After a total laryngectomy, the food passage may dilate to mimic an airway, but the laryngeal landmarks are no longer seen. Lower CT or MRI slices show the tracheostomy site.

The appearance of the glottic and subglottic levels is unchanged by a supraglottic laryngectomy. With the supraglottic larynx removed, the characteristic landmarks of the paraglottic and preepiglottic spaces are not identified. Usually, the hyoid bone is removed. The major portion of the thyroid cartilage above the level of the cords is also removed.

The vertical hemilaryngectomy can produce a variable appearance. One cord is removed, leading to significant asymmetry at the glottic level. Part of the upper larynx is removed on the ipsilateral side. The position of the original lesion dictates the position of the cuts through the thyroid cartilage, resulting in significant variability in appearance among patients with vertical hemilaryngectomies. At times, the surgeon may attempt to reconstruct the cord using a small slip taken from the strap muscles. This can lead to significant soft tissue that cannot be readily distinguished from tumor.

Radiotherapy can cause characteristic apparent swelling of the soft tissues over the arytenoid cartilage and supraglottic region. Subtle reticulation or stranding of the supraglottic fat is seen. Initially, this represents local inflammation and edema, but small-vessel changes make the appearance more permanent.

Trauma

Direct trauma can result in fractures or dislocations of the cartilages in the larynx. Soft tissue injuries such as

Figure 18–20. Saccular cyst (laryngocele). *A*, Postgadolinium T1-weighted axial image through the upper epiglottis shows the cyst (*C*). *B*, Slightly lower image shows the cyst (*C*) in the paraglottic space at the false cord level. The mucosa (*arrowhead*) is intact. *C*, Axial image through the true cord level shows no evidence of tumor. *A*, arytenoid; *T*, thyroid. The thyroarytenoid muscle (TAM) is shown by an *arrow*. *D*, Coronal image shows the lower margin of the lesion (*arrow*) above the upper edge of the TAM (*arrowhead*); thus, the cyst is above the ventricle.

Figure 18-21. Saccular cyst (laryngocele). *A*, The cystic structure has both an internal and external component. The saccular cyst (C) protrudes through the thyrohyoid membrane, approximately at the arrowheads. Note the sharp margin of the cyst. *B*, Slightly lower slice shows the dilated appendix (arrow) just above the ventricle. Again, note the sharp margin. The fat in the paraglottic space indicates that this is still above the ventricle. A normal appendix is on the opposite side (arrowhead).

Figure 18-22. Saccular cyst (fluid-filled laryngocele). *A*, The saccular cyst (L) is seen filling the paraglottic space at the level of the false cord. Note the intact mucosa (white arrow). The paraglottic fat on the normal side (arrowhead) remains of high signal intensity. Fat is shown in the thyroid cartilage (black arrow). *B*, Slightly lower slice shows a tumor (T) filling the ventricle and causing the obstruction of the ventricular appendix, causing the saccular cyst. (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

Figure 18-23. Thyroglossal duct cyst. The cystic structure (arrow) is seen on the outer surface of the thyroid cartilage intimately associated with the strap muscles. Note that the paraglottic fat (arrowhead) remains clear.

mucosal tears and hematomas can occur in isolation but are often seen in conjunction with fractures. CT scanning is usually used because of the ability to visualize the calcified cartilage and because of the speed of imaging. The fragile airway is more easily managed and monitored in the CT scan than in the more confined area of the MRI study.

In young patients, the cartilage may not be calcified but it can often be seen as slightly increased density against the contiguous soft tissues.

Fractures usually affect the thyroid or cricoid cartilage. The thyroid cartilage can have vertical or horizontal fractures (Fig. 18-24). Vertical fractures are easily detected in the axial scan plane, but horizontal fractures may be undetectable unless there is some displacement of the fracture fragments. Reformatted images may help to define horizontal fractures.

Figure 18-24. Vertical fracture of the larynx; axial CT. The arrow indicates a fracture.

The cricoid fracture is, characteristically, a double break (Fig. 18-25). The force of the blow pushes the anterior arch posteriorly, fracturing the ring in two or more places. The ring collapses inward. There is swelling in the subglottic soft tissues, giving apparent soft tissue against the inner surface of the cricoid cartilage, where normally the mucosa is very thin or almost invisible at imaging.

Compromise of the airway is a concern. Any inward displacement reduces the lumen of the airway. Equally of concern is the possibility of a tear of the mucosa. A fracture fragment protruding through the mucosa often results in chondritis and chondronecrosis with further airway restriction. If there is any suspicion of a fragment pushed toward the airway, direct visualization, at endoscopy or at open exploration, is indicated for a thorough assessment of the mucosa.

If there is sufficient force to fracture the thyroid cartilage, the lower epiglottis can be torn or avulsed. This situation can be seen, particularly with horizontal fractures where the fragments are pushed posteriorly, creating a shearing force across the lower epiglottis. Because the epiglottis does not calcify significantly, this abnormality is not detectable by CT scans. The only finding may be hematoma obscuring the fat in the preepiglottic space.

The arytenoid cartilage is not often fractured, but the cricoarytenoid joint can be dislocated (Fig. 18-26). This can occur with fairly minimal trauma to the lateral larynx or may result from more severe insult associated with fractures of the major cartilages. The arytenoid is normally perched just off midline. The radiologist tries to verify that the cartilage is in the normal position or grossly displaced. Currently, a subtle displacement cannot be confidently excluded.

The lower horns of the thyroid cartilage articulate with the lateral cricoid cartilage. This cricothyroid joint can theoretically be dislocated, usually in association with fractures of either the thyroid or cricoid cartilages. Because the attachment of the horn to the cricoid cartilage is fairly strong, a fracture of the lower horn is considered more common. One must be careful in making this diagnosis, since slight obliquity of the slice can cause apparent asymmetry of the space between the two cartilages. Each of the inferior horns must be followed down to the point of articulation.

Miscellaneous Problems

Although tumors and trauma account for most imaging of the larynx, imaging can be useful for several other problems.

Vocal Cord Paralysis

Vocal cord paralysis is most commonly a problem that affects the recurrent laryngeal nerve. All of the muscles in the larynx except the cricothyroid muscle are innervated by this nerve, but the most characteristic finding is the result of atrophy of the TAM. Normally, the TAM makes up the bulk of the true cord. With atrophy, the characteristic CT density or MRI intensity is no longer seen. The ventricle enlarges into the volume vacated by the atrophied muscle so that air can be seen where there should be

Figure 18-25. Fracture of the cricoid cartilage; the ring has been fractured. Fragments from the anterior ring (arrowheads) have been pushed back into the airway. These fragments would be in danger of perforating the mucosa. The lamina of the cricoid (arrow) is not fractured. Note the air in the soft tissues and the soft tissue within the ring of the cricoid cartilage. (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: Current Practice of Radiology, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

muscle. The vocal ligament remains, and the arytenoid cartilage may be in a fairly normal position or may be tipped slightly. The piriform sinus on the affected side often enlarges as well.

The posterior cricoarytenoid muscle is very thin, but since the axial plane provides a perfect cross-section, atrophy of this muscle may also be appreciated.²² In this case, fat appears to be closely applied to the posterior surface of the cricoid cartilage instead of the typical muscle density.

In most instances, atrophied muscle is seen in patients with known paralysis. If the cause of the paralysis is not known, the course of the vagus nerve and the recurrent laryngeal nerve is examined. CT scanning is usually performed because of the distance that must be covered and because bone detail is important at the level of the jugular foramen in the temporal bone. The nerve is just posterior

to the carotid artery and jugular vein on transit through the neck. Lower in the neck, the nerve moves forward with respect to the carotid artery. The left nerve loops around the aortic arch, and the right nerve loops around the subclavian artery. The nerve on both sides ascends along the tracheoesophageal groove to reach the larynx. A lesion at any level can involve the nerve and cause paralysis.

Superior laryngeal nerve paralysis is much less common, and characteristic radiographic findings have not been described. An extremely rare paralysis is "adductor paralysis." In this form, all muscles innervated by the recurrent laryngeal nerve are affected except the posterior cricoarytenoid. This muscle, unopposed, rotates the arytenoid and the cord laterally. This rare form of paralysis is not as well understood as the other more common paralyses but is thought to be related to an intracranial pathologic process.

Figure 18-26. Arytenoid dislocation. A, CT axial slice through the level of the cricoarytenoid joint. There is a normal configuration on the right. The arytenoid cartilage (arrow) articulates normally with the small articular surface of the cricoid (arrowhead) on the superior edge of the cricoid cartilage. The arytenoid on the left is not identified in a normal position. B, Higher slice shows the dislocated arytenoid (arrow) in the supraglottic area.

Stenosis

Subglottic stenosis and tracheal stenosis can be evaluated by plain films, but imaging can give information about the cross-sectional area of the remaining airway. CT can show narrowing or stenosis of anterior and posterior commissures. The position of the cartilage relative to the airway can also be visualized. CT scans can determine whether the cartilage has collapsed into the airway or whether the cartilage remains in the normal position with the stenosis related only to soft tissue.

Such narrowing can be congenital or may be the result of trauma. Granulation tissue can develop after tracheostomy. The length of the narrowing and the relationship to the vocal cords should be estimated. Plain films can be very helpful in estimating the length of the abnormality.

Granulomatous Disease

Granulomatous disease, either of infectious or noninfectious etiology, can involve the larynx. Although rare, it can involve any of the mucosal surfaces and can be mistaken for tumor. The findings at imaging are nonspecific.

Rheumatoid Arthritis

Rheumatoid arthritis can involve the cricoarytenoid joint. This process is not usually evaluated radiologically.

Polychondritis

Relapsing polychondritis is a rare disease of unknown etiology. The cartilages of the larynx and trachea (among others) become inflamed, with edema of surrounding tissues. Calcifications of the abnormal tissue are characteristic and can be highly prominent. If calcifications are particularly prominent, the increased soft tissues and calcifications can mimic chondroid lesions.

Summary

CT or MRI can be done for tumor imaging. One approach is to do CT as a first step, reserving MRI for answering specific questions remaining after CT. MRI is then done in a small fraction of cases. At our institution we begin with MRI in those cases where supraglottic laryngectomy is contemplated. This is because of a preference for MRI when looking at the region of the ventricle and the thyroarytenoid muscle. Contrast-enhanced CT scans are preferred for imaging of submucosal masses. CT scans are done without enhancement in trauma cases.

Nasopharynx and Oropharynx

Sherif Gamal Nour, Jonathan S. Lewin

The pharynx is a fibromuscular tube that forms the upper part of the aerodigestive tract. It extends from the skull base down to the C6 vertebral level, serving as a conduit that conveys both air and food to the respiratory and alimentary tracts, respectively. The nasopharynx, oropharynx, and hypopharynx (laryngopharynx) are the three classic pharyngeal subdivisions that lie directly on the spine behind the nose, oral cavity, and larynx, respectively. The nasopharynx and oropharynx constitute the suprahyoid part of the pharynx. Formed of a thin muscle layer, the pharyngeal wall is lined by a mucous membrane and covered by loose fascia that permits pharyngeal movement during deglutition.^{113, 116}

A diverse range of pathologic conditions may involve the nasopharynx and oropharynx. These may occur primarily within the layers of the pharyngeal wall or in the deep suprahyoid neck spaces adjacent to the pharynx, or they may protrude from the nose or skull base to hang in the airway as pharyngeal masses. In addition, pharyngeal disease may be a consequence of functional rather than anatomic derangement.

Prior to the modern imaging era, few tools were available for investigating pharyngeal disease. Having no more than a lateral plain x-ray, a conventional tomogram, or a contrast laryngopharyngogram, the radiologist had to depend on such signs as soft tissue fullness, intraluminal filling defects, and abnormalities in the pharyngeal margins imaged in profile¹⁴⁵; all of these signs constituted indirect evidence of pathology, yet no means existed to visualize the actual disease process.

Although amenable to clinical inspection, pharyngeal mucosal lesions may be difficult to evaluate because of anatomic variations and patient compliance.¹⁴⁵ A mucosal lesion, as detected by endoscopy, may represent no more than the "tip of an iceberg," with the exact deep extent always remaining uncertain to the endoscopist. Moreover, associated cervical lymph nodes, unless of palpable size, may be overlooked in the clinical setting.

The advent of cross-sectional imaging exemplified in computed tomography (CT), then magnetic resonance imaging (MRI), has revolutionized the diagnosis of pharyngeal and deep neck disease. For the first time, the radiologist was able to gain true insight into the actual pathology, to define its exact site of origin, to map out its extent, and to study its effect on vital neighboring neck structures. With this wealth of information, the radiologist could interact with the clinician in a more effective manner and could make invaluable contributions to treatment decision making.

The improved understanding of the complex suprahyoid neck anatomy offered by these modern imaging modalities has led to the development of a new approach to the diagnosis of pathologic conditions involving this region that utilizes the concept of fascially defined spaces rather than the classic pharyngeal subdivisions. As CT and MRI have become the basic tools for evaluating nasopharyngeal and oropharyngeal pathology, the current classifications of nasopharyngeal and oropharyngeal carcinomas adopted by the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) are now based on cross-sectional imaging findings.

The continuing evolution of MRI has gone beyond the mere imaging of anatomic changes to approach near real-time recording of the functional status of the pharynx, and the time is not far before the radiologic focus of interest broadens to include disorders of pharyngeal function, such as obstructive sleep apnea.

Finally, interventional MRI is a rapidly growing part of current radiologic practice and has been successfully applied to the pharynx and adjoining deep neck spaces to guide biopsies and minimally invasive therapeutic procedures.

Anatomy

The topics to be discussed are summarized in Box 19-1.

Traditional Classification

Classically, the suprahyoid head and neck region is divided into the nasopharynx, oropharynx, and oral cavity (Fig. 19-1), with the exact contents of each compartment dependent on how much of the adjoining deep tissues are included.^{4, 65, 128}

Nasopharynx

The *nasopharynx* is the uppermost part of the aerodigestive tract. It measures approximately 2 × 4 cm in anteroposterior and craniocaudal diameters, respectively. It is bounded posterosuperiorly by the basisphenoid, basiocciput, and upper two cervical vertebrae as well as by the prevertebral muscles.^{65, 108, 113, 128}

Anteriorly, it communicates with the nasal cavity through the choana. Inferiorly, it is in direct continuity with the oropharynx, and the plane of division is a horizontal line drawn along the hard and soft palates and passing

open mouth). It is separated from the oral cavity by the circumvallate papillae of the tongue, the anterior tonsillar pillars, and by the soft palate. The posterior third of the tongue and lingual tonsil are therefore considered to be within the oropharynx and not in the oral cavity.⁶⁵

Posteriorly, the superior and middle constrictor muscles separate the oropharynx from the prevertebral muscles overlying the second and third cervical vertebrae.

Superiorly, the oropharynx communicates with the nasopharynx.

Inferiorly, it is separated from the hypopharynx by the pharyngoepiglottic fold and from the larynx by the epiglottitis and glossoepiglottic fold.^{65, 119, 128}

The features of the lateral oropharyngeal walls include two faucial arches:

1. The anterior (palatoglossus muscle) arch.
2. The posterior (palatopharyngeus muscle) arch.

Between them lies the tonsillar fossa, which contains the palatine tonsil on each side.¹¹⁹

Spatial Approach

Although the classic classification of nasopharynx, oropharynx, and hypopharynx is quite effective in regard to superficial mucosal lesions, such as squamous cell carcinoma, this "non-fascially based" classification is much less helpful to the radiologist attempting to accurately localize deeply seated head and neck lesions as evaluated on cross-sectional imaging.^{4, 65}

The traditional classification of the suprahyoid head and neck into the nasopharynx, oropharynx, and oral cavity has thus been largely replaced by a somewhat complicated, yet more useful scheme that divides this region into multiple spaces, defined by the layers of cervical fascia. Such a "spatial approach" provides a satisfactory means of localizing the space of origin of a suprahyoid lesion and, consequently, helps to limit the differential diagnosis to a unique set of pathologic processes specific to each anatomic space.^{4, 40, 65, 67, 128, 162} Moreover, it utilizes surgically and pathologically defined terminology, thereby creating a "common language" for the radiologist and the referring surgeon.⁶⁵

posteriorly to the *Passavant's ridge* (a ridge of pharyngeal musculature that opposes the elevated soft palate).^{65, 108, 113, 128, 142} The features of the lateral nasopharyngeal walls are discussed later.

Oropharynx

The oropharynx is the part of the aerodigestive tract that lies behind the oral cavity (it can be seen through the

Figure 19-2. Diagrammatic layout of the suprahyoid neck spaces and their fascial boundaries at the level of the nasopharynx (A), detail of the nasopharynx (inset), and the oropharynx (B).

Crucial to an appreciation of suprahyoid neck spaces is a proper understanding of the fascial framework of the head and neck (Fig. 19-2; see Figs. 19-5 and 19-6). For the sake of completeness, each of these spaces is addressed here, with particular emphasis given to those most relevant to the subject of this chapter.

Basically, two major compartments constitute the head and neck fasciae: the superficial and deep layers.

Superficial Fascia

The superficial fascia is a loose fatty layer, with the platysma muscle embedded in its deep portion.^{61, 87}

Deep Fascia

The deep fascia is a complex of multiple sheets, which are generally subdivided into three layers:

- A superficial layer (investing fascia)
- A deep layer (prevertebral fascia)
- A middle layer (visceral fascia)

Superficial Layer of the Deep Fascia (Investing Fascia)

Description

The superficial layer forms a complete collar around the neck and is attached *superiorly* to the lower border of the mandibular body back to its angle and more posteriorly to the mastoid processes, the superior nuchal line, and to the external occipital protuberance.

Inferiorly, this layer attaches to the acromion and spine of the scapula, to the clavicle, and to the manubrium sterni. The two halves of the investing fascia attach *posteriorly* to the ligamentum nuchae and cervical spinal processes.

Anteriorly, they are continuous and are attached to the hyoid bone, where they converge with the middle (visceral) layer of the deep fascia, dividing the neck into suprahyoid and infrahyoid portions.^{61, 113}

Spaces

The investing fascia splits to enclose number of structures within the neck, thereby forming the following fascial spaces:

Masticator Space. Above the attachment to the lower border of the mandible, a part of the investing fascia continues upward to enclose the muscles of mastication and the mandible (ramus and posterior body) by splitting into a superficial and a deep layer. The superficial layer covers the masseter muscle and then attaches to the zygomatic arch (this is continuous with the fascia covering the parotid gland forming the parotid-masseteric fascia). The deep layer runs deep to both pterygoid muscles to attach to the skull base, separating the masticator from the prestyloid compartment of the *parapharyngeal space* (PPS).^{40, 61, 64, 70}

Parotid Space. The parotid space is formed as the investing fascia splits between the mastoid process and the angle of the mandible to enclose the gland, forming its capsule.^{14, 16} The medial aspect of the parotid space, which contains the deep lobe of the parotid gland, extends through the stylomandibular tunnel (the gap between the styloid process and the posterior margin of the mandible) for a variable distance before it meets the prestyloid compartment of the PPS.⁸⁷

Submandibular and Sublingual Spaces. A layer of the investing fascia splits to line the undersurface of the submandibular gland before reattaching to the mandible at the mylohyoid line, thereby forming the capsule of the gland. In the radiologic literature, the term *submandibular space* is given to the entire area superficial to the mylohyoid muscle down to the superficial layer of investing fascia as it extends from the hyoid bone to the mandible. The *sublingual space* is the area deep to the mylohyoid muscle, up to the mucosa of the mouth floor. The relevance of these spaces to this chapter is their free communication with the prestyloid compartment of the PPS.^{70, 87}

Muscular Spaces. Muscular spaces are formed as the fascia splits to enclose the trapezius, the sternocleidomastoid, and the inferior belly of the omohyoid muscles.^{61, 70}

Suprasternal Space (of Burns). This shallow space is formed just above the manubrium sterni as the investing fascia splits to attach to the anterior and posterior borders of the jugular notch.^{61, 70}

Deep Layer of the Deep Fascia (Prevertebral Fascia)

Description

The deep layer encircles the vertebral column as well as the paraspinal and prevertebral muscles, with a firm insertion on the spinous and transverse processes of the vertebral column. The prevertebral fascia extends from the skull base down to the third thoracic vertebra, where it fuses with the anterior longitudinal ligament in the posterior mediastinum.^{61, 113} Some authors have described a slip of the prevertebral fascia, the alar fascia, which is immediately anterior to it and has a similar coronal plane of orientation.^{61, 87}

Spaces

Perivertebral Space. The perivertebral space (PVS) is enclosed by the circumferential prevertebral fascia and is divided by the fascial attachment to the cervical transverse processes into the anterior prevertebral and posterior paraspinal compartments.^{65, 67, 128} This space extends from the

skull base to the coccyx and is tight enough to resist the superoinferior spread of infection or neoplasms.¹³²

Danger Space. This thin potential space lies between the prevertebral fascia posteriorly and the alar fascia anteriorly. The space is named as such because it extends from the skull base to the level of the diaphragm and is filled with loose areolar tissue, which provides a ready conduit for the spread of infection.¹³²

Middle Layer of the Deep Fascia (Visceral Fascia)

Description

There has been considerable confusion in the literature concerning the layers composing the visceral fascia, with most of the anatomic references focusing mainly on the pretracheal fascia in regard to the fascial layers between the investing and prevertebral fasciae.^{61, 113} However, to give the reader a full understanding of the spatial anatomy of this region, it would be more appropriate in this context to stress the layers relevant to the suprahyoid neck. The following basic fascial planes comprise the visceral fascia above the hyoid bone.

Buccopharyngeal Fascia. This fascia is a thin layer of loose connective tissue that covers the pharyngeal constrictor muscles and permits pharyngeal movement. It attaches superiorly to the skull base, having the same attachment as the pharyngobasilar fascia (see later), and is continuous anteriorly over the buccinator muscle.^{65, 70, 113, 119, 128} The buccopharyngeal fascia is not visible on CT scans or MR images.⁸³

Cloison Sagittale. These bilateral, small, sagittally oriented fascial slips extend from the buccopharyngeal fascia anteriorly to the prevertebral fascia posteriorly, near its attachment to the transverse processes of the cervical vertebrae. The importance of these tiny fascial slips is that they separate the medially positioned *retropharyngeal space* (RPS) from the laterally positioned retrostyloid compartments of the PPS.⁸⁷ These slips are sometimes also called the *alar fascia*, but this term is better avoided to prevent confusion with the alar fascia described earlier.⁸⁷

Fascia of Tensor Veli Palatini. This relatively thick fascial sheet envelops the styloid process and its musculature and extends anteromedially to merge with the fascia associated with the tensor veli palatini muscle. It then continues further anteriorly to fuse with the pterygomandibular raphe and the buccopharyngeal fascia.^{40, 158} This fascial layer divides the PPS into anterolateral (prestyloid) and posteromedial (retrostyloid) compartments.^{40, 158}

Pharyngobasilar Fascia (Pharyngeal Aponeurosis)

This important fourth fascial sheet lies between the superficial and the deep layers of the deep fascia, but it is usually considered to be separate from the middle layer. As a tough membrane, it forms an almost closed, very resistant chamber that determines the configuration of the nasopharynx.^{83, 142} It attaches superiorly to the skull base from the medial pterygoid plates, passing posteriorly to the petrous bones just anterior to the carotid foramina, where it reflects medially on either side to be continuous over the longus capitis and rectus capitis muscles. The fascia de-

scends from the skull base, forming an elongated ring that closes the gaps above the superior constrictor muscle of the pharynx bilaterally.

References on anatomy describe the fascia to then continue lining the inner surface of the pharyngeal musculature, thereby supporting the mucous membrane of most of the nasal portion of the pharynx, then it becomes much thinner below, at about the level of the soft palate.^{70, 83, 96, 113, 119, 128} From the functional and imaging perspectives, the most relevant portion of the pharyngobasilar fascia is that above the superior constrictor muscle, hence the name the *pharyngeal aponeurosis* (see Fig. 19–5). Formed of dense fibrous tissue, the pharyngobasilar fascia shows up on MRI images as a low-intensity line extending from the medial pterygoid plate to the carotid foramen medial to the tensor palatini.⁸³

Thus, the constrictor muscles of the pharynx are “sandwiched” between the pharyngobasilar fascia (inside) and the buccopharyngeal fascia (outside). Above the upper edge of the superior constrictor muscle (between it and the skull base), the two fascial layers blend to form, along with the lining mucosa, the thin wall of the lateral pharyngeal recesses (fossae of Rosenmüller).^{83, 96, 113} Anterior to these recesses, a natural defect in the pharyngobasilar fascia (sinus of Morgagni) exists on each side, transmitting the eustachian tubes and levator veli palatini muscles from the skull base to the *pharyngeal mucosal space* (PMS).^{83, 96, 119, 128} The torus tubarius, the most prominent anatomic landmark on the lateral nasopharyngeal walls, is a ridge lying between the orifice of the eustachian tube anteroinferiorly and the fossa of Rosenmüller posterosuperiorly on each side. It is formed by the levator veli palatini muscle together with the cartilaginous eustachian tube and the overlying mucosa.^{83, 96, 119}

Spaces

The deep face and neck spaces, defined by the just-described layers of visceral fascia, are presented next.

Pharyngeal Mucosal Space. The PMS is the area of the nasopharynx and oropharynx on the inner (airway) side of the buccopharyngeal fascia. The latter separates the PMS from the PPS laterally and the RPS posteriorly. The PMS is thus composed of the five layers forming the pharyngeal wall. From internal to external, they are as follows¹¹³:

1. *Mucous membrane.* The upper part of the nasopharynx is lined by respiratory epithelium (pseudostratified ciliated columnar). Inferiorly, where food contact is more of an issue, the epithelium changes to a stratified squamous type.⁹⁶
2. *Submucosa.* The submucosa contains minor salivary glands and prominent lymphoid tissue of Waldeyer’s ring (adenoids, palatine tonsils, lingual tonsils, and submucosal lymphatics). Lymphoid tissue may also normally be present in the epithelium (lymphoepithelium).^{65, 96, 128}
3. *Dense pharyngobasilar fascia.*
4. *Superior constrictor muscle of the pharynx.* Above this muscle, layers 3 and 5 are adherent and are pierced by the eustachian tube (cartilaginous end) and the levator palatini muscle, which are considered within the PMS.
5. *Thin buccopharyngeal fascia.* This fascia forms the outer confinement of the PMS.

Retropharyngeal Space. The RPS^{87, 128} is a small, potential space that is bounded as follows:

1. *Anteriorly* by the buccopharyngeal fascia, separating it from the PMS.
2. *Posteriorly* by the prevertebral fascia, separating it from the perivertebral space.
3. *Laterally* by the cloison sagittale, separating it from the retrostyloid compartment of the PPS on each side.⁸⁷
4. *Superiorly* by the skull base.
5. *Inferiorly* by the fusion of the buccopharyngeal and prevertebral fasciae between the T2 and T6 spinal levels.⁴⁵

The RPS normally contains a small amount of fat and, in the suprahyoid region, the lateral (nodes of Rouviere) and medial retropharyngeal lymph nodes.^{45, 65}

The medial retropharyngeal lymph nodes are located near the midline and are seldom seen unless they are pathologically enlarged.^{39, 45} The lateral retropharyngeal (LRP) lymph nodes are found immediately medial to the internal carotid artery, adjacent to the longus capitis muscle, and are usually most prominent at the C1–C2 level but can occasionally be visualized down to the level of the palate.^{39, 45, 101} The LRP nodes are usually identified on MR images and, to a lesser extent, on CT scans.

In adults, the nodes are usually smaller than 3 to 5 mm, but nodes of up to 1 cm can be considered normal if they are homogeneous.^{45, 101} In children, the LRP nodes may be as large as 2 cm in size, particularly if the adenoids are prominent.³⁹ This lymph node chain provides drainage for the nasopharynx, oropharynx, middle ear, nasal cavities, and paranasal sinuses.^{39, 132}

Parapharyngeal Space. The PPS is an anatomic recess, shaped like an inverted pyramid with its base at the base of the skull and its apex at the greater cornu of the hyoid bone. It occupies the space between the muscles of mastication and the deglutitional muscles.^{40, 67, 131, 156, 158} It has the following boundaries and relations:

1. *Laterally*
 - a. *Anterolaterally*; separated from the masticator space by the layer of investing fascia covering the medial aspect of the medial pterygoid muscle.^{28, 96, 119, 158}
 - b. *Posterolaterally*; separated from the parotid space by the layer of investing fascia covering the deep lobe of the parotid gland.^{119, 158} However, this is a sparse fascial layer that does not present a barrier to the spread of disease.⁸⁷
2. *Medially*; separated from the PMS by the buccopharyngeal fascia, while its extreme posterior part is separated from the RPS by the cloison sagittale.^{103, 128, 158}
3. *Posteriorly*; separated from the perivertebral space by the prevertebral fascia.^{103, 119, 158}
4. *Anteriorly*
 - a. *Anterosuperiorly* (at the level of the pterygomandibular raphe); closed by the convergence of the buccopharyngeal fascia with the fascia covering the medial aspect of the medial pterygoid muscle.^{87, 119}
 - b. *Anteroinferiorly* (at the level of the mylohyoid muscle); PPS is often continuous with the sublingual and submandibular spaces, thereby allowing lesions to

pass from one space to another without crossing a fascial boundary.^{36, 65, 70}

5. **Inferiorly**; PPS is generally described as extending down to the hyoid bone; however, the fusion of multiple fascial layers and muscle sheaths near the angle of the mandible limit the caudal extent of the space,⁸⁷ and the styloglossus muscle can be considered the functional inferior boundary of the PPS.⁸⁷

The PPS, as just defined, is a larger area of the deep face than the fatty triangles seen on either side of the

pharynx. This definition, which is supported by most authors, implies the division of the PPS by the fascia of tensor veli palatini (see earlier) into the following^{87, 131}:

1. **Prestyloid PPS**, anterolateral to the fascia.
2. **Retrostyloid PPS**, posteromedial to the fascia. This is the suprahyoid extension of the carotid space (carotid sheath and its contents).

The contents of the suprahyoid neck spaces along with the common disease processes involving each space are listed in Table 19–1.

Normal Imaging Anatomy

The anatomy of the normal suprahyoid neck, as seen with CT and MRI, is demonstrated in Figures 19–3 to 19–6.

Imaging Rationale and Techniques

CT and MRI are currently the primary modalities for investigating the suprahyoid neck region. This region,

which extends from the skull base to the hyoid bone, is surrounded, for the most part, by bones that limit external clinical examination. In addition, while the superficial extent of mucosal lesions can be readily identified by the examining physician, their deep extent as well as lesions confined to the deep spaces are almost totally inaccessible for clinical or endoscopic evaluation.

In many cases of suprahyoid neck masses, MRI offers benefits over CT because of its higher soft tissue contrast resolution, multiplanar capability, and superiority in detecting perineural tumor spread and intracranial invasion.⁶⁵

Computed Tomography

Patient Positioning

Patients are examined in the supine position for axial scans and in the prone position for direct coronal scans. The prone position is recommended whenever a nasopharyngeal or palatal mass is suspected and there is a possibility of skull base erosion.¹¹⁹ Scanning is done during suspended respiration and attention must always be paid to proper head position.¹¹⁹

Intravenous Contrast

A confident assessment of the possible cervical lymphadenopathy associated with nasopharyngeal and oropharyngeal pathology requires optimal vascular opacification with an iodinated contrast medium. This is achieved by delivering a loading bolus (50 mL, 2 mL/second) via a power injector, followed by continuous contrast infusion (1 mL/second).¹¹⁹

Acquisition Parameters

A preliminary lateral scout view is obtained. Axial scans are planned parallel to the infraorbital-meatal line and should cover the whole region from the external auditory canal to the upper border of the manubrium sterni. Such extended coverage ensures proper evaluation of the pharynx, skull base, and all node-bearing areas. Examination is

best performed with 3- to 5-mm-thick contiguous slices and a small field of view (FOV). An additional high-resolution bone reconstruction algorithm should be used to evaluate any pathologic bone involvement.^{81, 119}

Magnetic Resonance Imaging

Patient Positioning

Axial, sagittal, and coronal scans are obtainable without the need to reposition the supine patient. A head coil is convenient for scanning the nasopharynx and oropharynx. In patients with malignancies, since the entire neck must be evaluated for nodal disease, a dedicated neck coil must be used in addition in order to cover the area from the mouth floor to the supraclavicular region.^{83, 96, 119} Besides head motion, pharyngeal motion (e.g., swallowing and snoring) must also be prevented to ensure optimal image quality.¹¹⁹

Intravenous Contrast

Postintravenous gadolinium-DTPA T1-weighted studies are helpful in detection of pathologic lesions. Such images improve the visualization of small lesions; provide excellent evaluation of lesion extension, subtle infiltration, and perineural spread; and aid in the assessment of tumor recurrence after radiotherapy or surgery.^{108, 128, 140, 177}

Pulse Sequences and Acquisition Parameters

In general, T1-weighted images provide the best fat-muscle and fat-tumor contrast, whereas T2-weighted images provide the best muscle–lymphoid tissue contrast.^{95, 119, 171}

The axial plane is often most useful, and both axial T1-weighted and T2-weighted images, encompassing at least the region from the palate to the hyoid bone, should be performed in all cases. It is recommended that T2-weighted images, using a fast spin-echo with fat-suppression technique, be acquired because this method yields very high conspicuity of lesions.^{89, 128}

Coronal T1-weighted images improve the evaluation of lesions adjacent to the skull base and within the subman-

dibular or sublingual spaces, and sagittal T1-weighted images are helpful in the evaluation of midline lesions.

Contrast-enhanced T1-weighted images are also best obtained with the use of fat-suppression techniques in order to achieve better definition of the enhanced areas, particularly for blocking the marrow signal in the evaluation of the skull base or other involved bone. However, suboptimal fat-suppression techniques may create artifactual bright signals that mimic pathologic processes, particularly in the high nasopharynx and in the low orbit.^{2, 128}

As stated, additional neck scanning for nodal metastases using a neck coil is required for patients with malignancies.

Slice thickness should be no more than 3 to 4 mm for T1-weighted images and 5 mm for T2-weighted images, with an interslice gap of 1 mm or less. For T1-weighted images, echo time (TE) should be kept as short as possible

in order to reduce the magnetic susceptibility artifact. Motion compensation gradients and spatial presaturation pulses may also be helpful in reducing flow and other motion artifacts. Phase encoding should be swept in an anteroposterior direction so that the vascular “ghost artifacts” are thrown anteroposteriorly and not across the pharyngeal tissues.⁶⁵ The optimal field of view, matrix size, and number of signal averages depend upon the particular imaging system and field strength, but they should reflect a compromise between adequate signal-to-noise, spatial resolution, and total examination length.

Several newer MRI techniques have been applied to nasopharyngeal and oropharyngeal imaging, including:

1. MR angiography for evaluation of vascular occlusion or displacement by a mass.^{128, 176}
2. Functional upper airway imaging to study the soft palate function in patients with sleep apnea and cleft palate.^{107, 128}
3. Perfusion imaging to assess tumor vascularity and response to treatment.

4. Spectroscopy to determine the primary presentation of malignancy and possible tumor recurrence.¹²⁸

Pathology

Lesions Arising within the Pharyngeal Wall and Adjoining Deep Neck Spaces

Lesions of the Pharyngeal Mucosal Space

Pseudomass

Asymmetric Fossae of Rosenmüller

Asymmetry of the lateral pharyngeal recesses may result from inflammatory debris or asymmetry in the amount of lymphoid tissue, thereby giving the impression of a mass in the PMS.^{42, 65, 128} A true tumor is ruled out when^{42, 65}:

1. The adjoining soft tissue planes in the PPS and RPS are maintained.
2. The nasopharyngeal mucosa is clinically intact.
3. The collapsed recess opens when rescanning by CT is used during the Valsalva maneuver.

Congenital Lesions

Thornwaldt's Cyst

Thornwaldt's cyst is a congenital midline posterior PMS cyst, lined by pharyngeal mucosa. It results from focal adhesion of pharyngeal mucosa to the notochord, which is then carried up as the notochord ascends to the developing skull base. A resultant nasopharyngeal diverticulum is created (a pharyngeal bursa),²⁸ whose orifice becomes obliterated after an attack of pharyngitis, thereby forming the cyst. Thornwaldt's cysts are present in 4% of all autopsy specimens (and MR images of the head).^{42, 65, 119}

Clinical Presentation. The peak age incidence is 15 to 30 years. Thornwaldt's cyst is usually an asymptomatic, incidental finding in head MRI. The cyst is usually infected with anaerobic bacteria, and when intracystic pressure increases, the orifice opens and the patient presents with persistent or periodic nasopharyngeal drainage, halitosis, and foul taste. Dull occipital headache has also been described.^{42, 65, 108, 119}

Imaging Features (Fig. 19-7). Thornwaldt's cyst ap-

pears as a well-circumscribed, thin-walled, midline (but may be slightly off-center) posterior nasopharyngeal mucosal space cyst lodged between the prevertebral muscles. It varies in diameter from a few millimeters to several centimeters. On CT scans, a small cyst may be missed whereas a larger one usually is seen as hypodense mucoid attenuation. CT attenuation of the cyst increases as does its protein content, and occasionally it may mimic a soft tissue mass. MRI readily identifies the cyst, whose T1-weighted signal intensity increases from low to high with increasing protein content.

On T2-weighted and fluid-attenuated inversion recovery (FLAIR) images, signal intensity is high.^{42, 65, 77, 119} Postcontrast studies show marginal enhancement.²⁸ Other imaging features may include superimposed cervical adenitis secondary to cyst infection.^{6, 11, 128}

Inflammatory Conditions

Adenoidal and Tonsillar Hypertrophy

Hypertrophy of these lymphoid tissues represents immunologic activity and not a disease process per se. It is most commonly seen in the adenoids,⁶⁵ which begins to be

Figure 19-7. Thornwaldt's cyst. A, Contrast-enhanced CT scan shows a small Thornwaldt cyst occupying the typical midline posterior nasopharyngeal location. Marginal enhancement delineates the otherwise isodense cyst (arrowheads). Axial T2-weighted (B) and sagittal postgadolinium-enhanced, T1-weighted (C) MR image of another Thornwaldt cyst. The T2-weighted image demonstrates a sharply defined, hyperintense mass lesion resting on the posterior nasopharyngeal wall and dipping between the longus capitis muscles. An internal septum is noted (white arrow, B). Rim enhancement is apparent on the postgadolinium-enhanced scan. The intermediate T1-weighted signal of the cyst denotes its high protein content. Note the incidental right-sided posterior fossa arachnoid cyst (c in B and C).

prominent by the age of 2 to 3 years and to regress from adolescence onward. Failure to visualize adenoidal tissue in a young child should raise the possibility of an immune deficiency state.¹¹⁹ In adults, smoking not uncommonly induces nasopharyngeal lymphoid hyperplasia.⁵³

Clinical Presentation. Infants present with difficulty in feeding, whereas older children present with other symptoms of nasal obstruction, such as mouth breathing and snoring. Otitis media may result from encroachment on the orifice of the eustachian tube.⁶⁵ Dysphagia may be caused by palatine tonsillar hypertrophy.^{13, 134} Adenoidectomy or

tonsillectomy is indicated when hypertrophy results in nasopharyngeal airway obstruction, chronic otitis media, or serous middle ear effusion.^{13, 58, 59}

Imaging Features (Fig. 19-8). Hypertrophic adenoids appears as a homogenous fullness of the nasopharyngeal mucosal space, which obliterates the fossae of Rosenmüller and encroaches upon the nasopharyngeal airway. On CT scans, the adenoid is isodense to the underlying prevertebral muscles and may contain small cysts and calcifications. On T1-weighted MRI scans, it is isointense to the muscles as well but can be identified by its bright T2-

Figure 19-8. Adenoidal hypertrophy.

A, Contrast-enhanced CT scan of the nasopharynx demonstrates enlarged adenoid tissue. The thin, enhancing line separating the adenoids (asterisk) from the prevertebral muscles represents the intact pharyngobasilar fascia, indicating that the mass is totally within the confines of the pharyngeal mucosal space. Also note the intact fat planes separating the mass from the lateral pterygoid (L) muscles on either side.

B-D, MR images at the level of the nasopharynx in a 10-year-old girl. B, Axial unenhanced, T1-weighted image (TR = 570 msec, TE = 14 msec) shows a homogeneous mass filling the nasopharyngeal airway and displaying an isointense signal to the adjacent muscles. C, Axial T2-weighted image (TR = 2500 msec, TE = 90 msec) more accurately identifies the adenoidal tissue as a bright signal casting the shape of the airway and well contrasted against the dark prevertebral muscles. D, Axial gadolinium-enhanced, T1-weighted MR image (TR = 594 msec, TE = 14 msec) elegantly demonstrates the pharyngobasilar fascia as a thin, enhancing line (arrowheads), marginating the deep and lateral adenoid surfaces and confirming the noninvasive nature of the lesion.

weighted signal. On postcontrast scans, the pharyngobasilar fascia normally enhances as a thin, continuous line outlining the deep adenoid surface.

Identification of this line is a reliable sign of the noninvasive nature of the mass, although it does not guarantee benign pathology.^{65, 119} In fact, it may be impossible to differentiate between hypertrophic adenoids and nasopharyngeal lymphoma on the basis of CT or MRI,⁴⁷ and a definitive diagnosis can be made only by biopsy. Other imaging features include reactive cervical adenopathy¹¹⁹ and eustachian tube dysfunction, which is best detected as bright T2 signals of fluid in the mastoid air cells.¹⁰⁸

Hypertrophic palatine tonsils are less common and present as bilateral, smooth oval, or rounded soft tissue masses encroaching upon either side of the oropharyngeal air column. Hypertrophic lingual tonsils are the least common. They occur at the tongue base and encroach posteriorly upon the valleculae. CT and MRI appearances of both are similar to those of adenoidal hypertrophy.⁷³

Tonsillitis and Peritonsillar Abscess

Acute tonsillitis or adenotonsillitis may be caused by viral or bacterial infection. The disease is usually self-limited, but when severe, infection may suppurate, resulting in a peritonsillar abscess (quinsy) or, rarely, in a tonsillar abscess. A peritonsillar abscess entails accumulation of pus in the tonsillar bed (between the tonsillar capsule and the faucial arches), with medial displacement of the tonsil. The abscess may further extend deeper into the neck to involve the PPS or lateral part of the RPS.^{73, 119} Peritonsillar abscesses constitute 49% of head and neck space infections in children.¹⁷³ When secondary to infectious mononucleosis, it is associated with cervical lymphadenopathy and hepatosplenomegaly.⁹⁶

Clinical Presentation. The patient is typically a child or a young adult. Patients with simple tonsillitis present with fever and sore throat. In a patient with peritonsillar abscess, initial tonsillitis may be followed by a few days of lucidity before the development of rapidly progressive dysphagia, otalgia, and perhaps trismus if the medial pterygoid muscle is involved. Pharyngeal wall protrusion is seen on clinical examination.^{65, 119}

Imaging Features. Imaging is rarely performed in the stage of acute, uncomplicated tonsillitis. When a peritonsillar abscess is clinically suspected, the radiologist's responsibilities are to^{65, 73}:

1. Confirm the diagnosis.
2. Determine the degree of airway compromise.
3. Determine whether the abscess is confined to the PMS or has spread into the PPS or the RPS.
4. Comment, in the case of a deeply extending abscess, on the status of internal carotid artery and internal jugular vein.

A peritonsillar abscess confined to the PMS appears as a diffuse, ill-defined thickening of the tonsillar region that bulges medially into the oropharyngeal airway with preserved parapharyngeal fat. On noncontrast CT scans, the inflammatory process appears hypodense to isodense.⁴² On MR images, it is also hypointense to isointense to the

surrounding muscles on T1-weighted images and hyperintense on T2-weighted images. Postcontrast studies are essential to delineate the enhancing rim of a mature abscess wall that requires drainage.¹⁸⁴

Imaging features of a deeply extending abscess are discussed later under the appropriate topics.

Postinflammatory Dystrophic Calcification

Clumps of tonsillar calcification (tonsilloliths) may be detected incidentally on CT scans (Fig. 19-9) and indicate previous or chronic tonsillitis. Less commonly, they are seen in the adenoids or the lingual tonsil.^{65, 128, 184}

Postinflammatory Retention Cyst

Postpharyngitis sequelae also include the formation of mucous retention cysts in the inflamed obstructed mucous glands. These cysts are similar to those that develop within the paranasal sinuses.^{4, 184}

Clinical Presentation. These retention cysts are usually asymptomatic but may be large enough to cause a superficial pharyngeal mass or otitis media secondary to eustachian tube orifice compromise.⁶⁵

Imaging Features. The cyst appears as a well-defined mass in the PMS. It is usually a few centimeters in diameter but can grow to a large size.^{65, 128} Both CT and MRI demonstrate the appearance of a typical cyst (i.e., hypodense on CT scans, dark on T1-weighted images, and bright on T2-weighted images). However, a high protein content increases CT density and T1-weighted signal intensity.

Benign Tumors

Juvenile Nasopharyngeal Angiofibroma

This angiofibroma is a highly vascular, benign yet locally invasive, noncapsulated mesenchymal tumor.^{108, 180} It

Figure 19-9. Dystrophic calcification of the faucial tonsils. CT scan at the level of the oropharynx shows bilateral clusters of tonsillar calcification (tonsilloliths), more evident on the left side.

is thought to arise near the sphenopalatine foramen^{28, 184} at the junction between the nose and the nasopharynx at the root of the medial pterygoid plate. It represents 0.5% of all head and neck neoplasms,⁴² and the incidence is higher in the Far East than in the United States.¹⁸⁴

Clinical Presentation. Juvenile angiofibroma occurs almost exclusively in adolescent boys,^{28, 184} with the mean age at presentation 15 years.⁴² The most common presenting symptom is nasal speech attributed to nasal obstruction (91%), the next most common is severe recurrent epistaxis (59%), and the least common is facial deformity.⁴² On examination, a dark red (probably ulcerating) mass is seen in the nasal fossa and postnasal space.¹³³

Imaging Features (Figs. 19–10 and 19–11). Juvenile angiofibroma appears on CT and MRI images as a soft tissue mass varying in size from a small nodule resting on the sphenopalatine foramen and striding the choana to a quite large, locally aggressive growth extending in any or a combination of the following directions:

1. *Posteriorly.* The tumor may protrude into or may totally fill the nasopharyngeal airway.
2. *Anteriorly.* The tumor may block and expand the ipsilateral nasal fossa. Large tumors may also extend directly into the contralateral nasal fossa through the choana.
3. *Medially.* The tumor may push the nasal septum significantly to encroach upon or even to obliterate the contralateral nasal fossa.
4. *Laterally.* In 90% of cases, the tumor extends laterally through the sphenopalatine foramen into the pterygopalatine fossa.⁶³ The fossa is widened with classic anterior bowing of the posterior maxillary antral wall along

with posterior displacement and, possibly, erosion of the pterygoid laminae. Bowing of the posterior antral wall (Holman-Miller sign)¹⁸⁴ is a nonspecific sign that can be produced by any slowly growing mass, whereas erosion of the pterygoid lamina is probably a pathognomonic sign.¹³³ From the pterygopalatine fossa, the tumor may further extend laterally through the pterygomaxillary fissure into the masticator space (infratemporal fossa).²⁸

5. *Superiorly.* In 65% of cases, juvenile angiofibromas erode the floor of the sphenoid sinus to invade the sinus cavity.¹⁸⁰ It is important to differentiate intrasinus tumor invasion from obstructed secretions.⁷³ This is best done by T2-weighted MRI. The ethmoid air cells may also be invaded.¹⁰⁸ Intraorbital extension, with subsequent proptosis, can occur from the pterygopalatine fossa through the inferior orbital fissure, which becomes widened.^{28, 42} Intracranial invasion (into the middle cranial fossa) can then occur from the orbit through the superior orbital fissure^{28, 42, 180} or by direct erosion of the roof of the sphenoid sinus.¹⁰⁸ Coronal scans are valuable for precise detection of superior tumor extension.
6. *Inferiorly.* The tumor can grow sufficiently to push the soft palate and bulge into the oropharynx and adjoining oral cavity.

On unenhanced CT scans, the tumor appears isodense; on MR images, it displays intermediate T1-weighted and strongly bright T2-weighted signal intensities. On both T1-weighted and T2-weighted images, characteristic punctate areas of signal void indicate the highly vascular stroma. Postcontrast CT and MRI reveal intense enhancement.^{42, 133, 180}

Figure 19–10. Juvenile nasopharyngeal angiofibroma. A, Axial contrast-enhanced CT scan demonstrates the typical features of nasopharyngeal angiofibroma (grade 2). A strongly enhancing mass lesion is centered on the markedly widened pterygopalatine fossa and is displacing the yet intact posterior maxillary antral wall forward. (Compare the distance between the dashed lines on the left side to the normal-sized basal part of the pterygopalatine fossa on the right side [black arrowhead].) The sphenopalatine foramen, where an angiofibroma is believed to arise, is located at a higher level above the asterisk. B, Coronal nonenhanced CT scan shows a large, isodense nasopharyngeal soft tissue mass in a 14-year-old boy. The mass occupies most of the airway and is eroding the root of the medial pterygoid plate (arrowhead) as well as the floor of the sphenoid sinus, yet without frank intrasinus extension.

Figure 19-11. Juvenile nasopharyngeal angiofibroma. MRI scan of a grade 3 angiofibroma in a 15-year-old boy.

A, Axial postgadolinium-enhanced, T1-weighted scan (TR = 779 msec, TE = 12 msec) shows a large, intensely enhancing mass centered on the left sphenopalatine foramen region. It totally occupies the nasopharyngeal airway, plugs both choanae, and extends into the nasal fossae, more on the left side. The mass extends laterally to cause marked widening of the pterygopalatine fossa, from which it emerges through the pterygomaxillary fissure into the masticator space (infratemporal fossa). Note the remodeling and anterior displacement of the posterior wall of left maxillary sinus as a result of chronic pressure.

B, Coronal nonenhanced, T1-weighted image of the same patient shows the angiofibroma as an intermediate signal soft tissue mass with multiple linear and punctate signal voids, representing the rich tumor vascularity. The mass is eroding the floor of the sphenoid sinus to fill and expand its left-sided compartment.

C, Coronal postgadolinium-enhanced, T1-weighted image shows the same patient at a different plane. The tumor has extended into the left cavernous sinus, abutting yet incompletely encasing the cavernous segment of the internal carotid artery. Such extension has probably occurred from the pterygopalatine fossa via the foramen rotundum.

The following imaging-based grading system of juvenile angiofibromas has been proposed.^{28, 136, 172, 184}

- *Grade 1*, tumor confined to nasopharynx
- *Grade 2*, tumor extending into pterygopalatine fossa or masticator space
- *Grade 3*, tumor extending into orbit or intracranially

This scheme would predict the prognosis and recurrence rate and would indicate the optimal surgical approach.

The high tumor vascularity contraindicates biopsy, and preoperative embolization is necessary. The primary supply is through the maxillary artery. Minor contributors include the ascending pharyngeal and ascending palatine branches

of the external carotid artery, and sometimes the tumor may have a supply from the internal carotid artery.^{42, 180, 184}

Benign Mixed Tumor of Minor Salivary Glands

Benign mixed tumor (*pleomorphic adenoma*) may arise in the minor salivary glands located in the submucosal layer of the PMS, soft palate (most common site), or tongue base. Extrapharyngeal sites include the mouth, nose, paranasal sinuses, larynx, and trachea.¹¹⁹

Clinical Presentation. The presentation varies from a small submucosal nodule to a large pedunculated mass that compromises the pharyngeal airway.⁶⁵

Imaging Features. When the tumor is small, it is best detected by MRI as a sharply demarcated, rounded, homogeneous PMS mass of low to intermediate T1-weighted and very high T2-weighted signal intensities.^{105, 184} CT and MRI show a larger tumor as a pedunculated mass encroaching upon the nasopharyngeal or oropharyngeal airway. The appearance is nonspecific, and a biopsy usually enables the diagnosis.^{65, 119}

Malignant Tumors

Squamous Cell Carcinoma

Nasopharyngeal Carcinoma. Squamous cell carcinoma (SCC) constitutes 70% of adult nasopharyngeal malignancies.^{108, 119, 124} These are further subdivided into¹⁴⁹:

- Type 1, keratinized squamous cell carcinoma (25%)
- Type 2, nonkeratinized carcinoma (12%) (sometimes called transitional cell carcinoma)
- Type 3, undifferentiated carcinomas (63%)

Several etiologic factors interact to predispose to the development of nasopharyngeal squamous cell carcinoma, such as:

- Genetic susceptibility
- Environmental factors (including chemical carcinogens)
- Exposure to Epstein-Barr virus,³⁰ which is very highly associated with types 2 and 3 of nasopharyngeal SCC^{33, 180, 184}

The highest incidence is found in southern China and southeast Asia²⁸ and is seven times higher in Americans of Chinese ancestry than in non-Chinese Americans.⁴⁶ A higher incidence is also found in African Americans.⁴⁹

Other risk factors include chronic sinonasal infection, nitrosamines (in dry-salted fish), polycyclic hydrocarbons, and poor living conditions.^{119, 124}

Most tumors arise in the fossa of Rosenmüller and tend toward submucosal spread to infiltrate the palatal muscles and eustachian tube orifice.^{28, 30}

Clinical Presentation. Nasopharyngeal carcinoma is more common in men, and most cases in the United States are diagnosed during the sixth decade of life.^{30, 119} Reports from southeast Asia, however, indicate middle age, adolescence, and even childhood presentation.¹⁷

Patients with early-stage disease may be asymptomatic or may present with nonspecific, commonly overlooked symptoms such as postnasal drip and nasopharyngeal irritation.¹⁰⁸ Middle ear effusion secondary to involvement of the eustachian tube orifice or tensor veli palatini muscle⁸⁰ is also an early sign, and older patients with otitis media should always undergo imaging to rule out nasopharyngeal tumors.⁴

Cervical lymphadenopathy prompting initial medical consultation is also a common presenting symptom.³⁰ Patients with advanced disease may present with nasal obstruction, epistaxis, trismus, proptosis, and various cranial nerve palsies; the trigeminal nerve is the most commonly involved.^{23, 28, 108, 119, 166}

Imaging Features

Early Cancer. As stated, most tumors arise in the lateral pharyngeal recess (fossa of Rosenmüller), and their signal intensity is almost similar to that of the adjacent mucosa.⁴² The earliest imaging sign is thus asymmetrical superficial nasopharyngeal mucosa. This sign, however, should be cautiously interpreted because physiologic asymmetry of the fossae of Rosenmüller does exist. In addition to the measures listed earlier in this section, careful attention must be given to the following^{4, 119, 178, 184}:

1. The fat stripe between the tensor and levator veli palatini muscles. Obliteration of the normally bright T1-weighted signal of this stripe may be one of the earliest indications of nasopharyngeal carcinoma (Fig. 19-12).
2. The ipsilateral middle ear and mastoid air cells. Detection of middle ear effusion or otomastoiditis as a bright

Figure 19-12. Nasopharyngeal carcinoma. Axial non-contrast-enhanced, T1-weighted MRI of the nasopharynx demonstrates a small, left-sided, isointense mass lesion in the pharyngeal mucosal space of the nasopharynx infiltrating the ipsilateral prestyloid parapharyngeal fat and barely touching the adjacent lateral pterygoid muscle. This appearance raises the possibility of masticator space invasion as well. Note the preserved fat stripe between the levator veli palatini muscle (arrow) and the tensor veli palatini muscle (arrowhead) on the normal right side.

T2-weighted signal is a warning sign of eustachian tube dysfunction.

3. Associated cervical lymphadenopathy. In particular, enlarged ipsilateral LRP lymph nodes (of Rouviere) presenting low to intermediate T1-weighted and high T2-weighted signals (Fig. 19–13).

Imaging of the entire neck with a dedicated neck coil is the essential next step, since up to 90% of these patients have cervical lymphadenopathy at presentation and about 50% have bilateral disease.^{108, 110, 119} Although the LRP nodes are considered first-echelon nodes, they are first involved in only 65% of cases and skipped in the remaining 35% of patients, in whom internal jugular nodes are involved without radiographic evidence of retropharyngeal node disease.^{30, 31}

Advanced Cancer. The most reliable sign of nasopharyngeal malignancy is the detection of an aggressive mass infiltrating the deep fascia and spaces around the nasopharynx (Fig. 19–14).^{100, 119} On CT, it appears as an isodense mass that does not show significant enhancement in the postcontrast study even when it is large.¹⁵⁴

On plain T1-weighted MR images, the tumor is isointense to the adjacent muscles.⁸¹ This sequence is valuable for detecting replacement of the high-signal fat in the deep fascial spaces with the intermediate-signal tumor. On T2-weighted images, the tumor displays intermediate to high signal intensity.^{119, 154, 178}

Considerable enhancement of the solid parts of the tumor occurs in the postgadolinium scans. Fat-saturated, postgadolinium T1-weighted images are particularly valuable for defining the extent of tumor infiltration into the marrow of the skull base or the retrobulbar fat while maintaining good contrast between the enhancing tumor and adjacent muscles.^{5, 126, 154} In addition, both fat-saturated,

postcontrast T1-weighted and fat-saturated T2-weighted sequences have been shown to improve the detection of lymphadenopathy as well as the presence of nodal necrosis or extracapsular nodal spread.^{5, 38, 69, 126}

Although CT is particularly helpful for detecting involvement of thin bony structures, such as the cortical bones of the skull base, paranasal sinuses, and orbits,^{30, 119, 154} MRI better delineates infiltration of bone marrow.³⁰ It is generally agreed that MRI is the modality of choice in the diagnosis of primary as well as recurrent nasopharyngeal carcinoma.^{29, 30, 76, 126, 127, 154} The imaging appearance is usually nonspecific for a particular type of malignancy, and CT and MRI images of squamous cell carcinoma may be almost identical to those of nasopharyngeal lymphoma or minor salivary gland malignancies.^{65, 119}

Role of Imaging

When evaluating cases of nasopharyngeal carcinoma, the radiologist has the following primary tasks¹⁸⁴:

- To provide accurate tumor staging
- To define tumor margins for the radiation oncologist
- To evaluate the response to radio/chemotherapy

The most recent (fifth) edition of the Tumor-Node-Metastasis (TNM) classification of nasopharyngeal carcinoma, published in 1997 as a collaborative project of the UICC and the AJCC, is given in Table 19–2.^{1, 174}

Nasopharyngeal carcinoma has been described as spreading along well-defined routes,^{30, 146} with a tendency to grow along the path of least resistance,^{108, 119} as follows:

1. **Lateral spread** is the most common direction.^{30, 119, 147, 165, 166, 186} The tumor creeps out of the PMS through the only dehiscence in the superolateral part of the tough pharyngobasilar fascia, the sinus of Morgagni, to reach the PPS.¹¹⁹ This pattern of spread occurs quite early and

Figure 19–13. Enlarged lateral retropharyngeal lymph node (of Rouviere). Nonenhanced, axial T1-weighted MR image at the level of the oropharynx shows the typical appearance of enlarged left-sided node of Rouviere (N) in a patient with nasopharyngeal carcinoma. The enlarged node appears as a well-defined paramedian retropharyngeal small soft tissue mass of intermediate T1-weighted signal intensity. It effaces and displaces the parapharyngeal fat anterolaterally and mildly rotates the oropharyngeal airway in a counterclockwise direction.

Figure 19-14. Nasopharyngeal carcinoma infiltrating the left parapharyngeal space.

A, Axial nonenhanced, T1-weighted MR image demonstrates a soft tissue mass ($\sim 4 \times 2.5$ cm) involving the left aspect of the pharyngeal mucosal space, bulging into the nasopharyngeal airway, and extending deeply into the ipsilateral prestyloid parapharyngeal space. (Compare the size and shape of parapharyngeal fat on both sides.) The imperceptible fat planes between the tumor and the lateral pterygoid muscle anteriorly and prevertebral muscles posteriorly suggest masticator and pervertebral space involvement.

B, Axial postgadolinium-enhanced, T1-weighted MRI scan shows considerable tumor enhancement and delineates the exact tumor boundaries except in relation to parapharyngeal fat, an issue already observed on the nonenhanced scan.

C, Axial T2-weighted MR image of the same patient shows a tumor of intermediate signal intensity. Note the associated fluid signal within the left mastoid air cells secondary to eustachian tube obstruction.

is seen in 60% of patients at presentation^{29, 184} as partial or complete effacement of the parapharyngeal triangle of fat (see Figs. 19-12 and 19-14). From there, the tumor may further extend laterally to break into the masticator space, infiltrating the pterygoid muscles and giving rise to trismus.^{19, 21, 30} Once the masticator space is violated, careful scrutiny should be made to detect the highly possible perineural infiltration of the mandibular nerve. The latter acts as a "cable" along which the tumor tracks upward to gain intracranial access through the foramen ovale, invade the gasserian ganglion in Meckel's cave (Fig. 19-15), and follow the preganglionic segment of the trigeminal nerve as far as the pons, often resulting in denervation atrophy of the muscles of mastication (Fig. 19-16).^{30, 65} Perineural spread is often

clinically silent until the intracranial segment of the nerve has been infiltrated.¹⁶⁶ Such perineural infiltration is best evaluated by precontrast and postcontrast coronal T1-weighted MRI, particularly with fat-suppression techniques.^{5, 166} The mandibular nerve, lying between the medial and lateral pterygoid muscles, demonstrates abnormal thickening and enhancement with effacement of the surrounding fat planes.^{82, 119} Imaging signs of perineural tumor spread are detailed later (see "Oropharyngeal Carcinoma").

2. *Posterolateral spread* occurs into the retrostyloid compartment of the PPS, thereby putting cranial nerves IX through XII at risk of involvement.³⁰
3. With *posterior spread*, the tumor first infiltrates the RPS, obliterating its fat stripe, then invades the periver-

**Table 19-2. Tumor-Node-Metastasis (TNM)
Classification of Nasopharyngeal
Carcinoma****T Staging**

T1	Tumor confined to nasopharynx
T2	Tumor extends to soft tissue of oropharynx and/or nasal fossa:
T2a	Without parapharyngeal extension*
T2b	With parapharyngeal extension*
T3	Tumor invades bony structures and/or paranasal sinuses
T4	Tumor with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, or orbit

N Staging

N0	No regional lymph node metastasis
N1	Unilateral node(s): 6 cm or less in greatest dimension above supraclavicular fossa
N2	Bilateral node(s): 6 cm or less in greatest dimension, above supraclavicular fossa
N3	Metastasis in lymph node(s):
N3a	Greater than 6 cm in dimension
N3b	In the supraclavicular fossa

M Staging

M0	No distant metastases
M1	Distant metastases are present

*Parapharyngeal extension denotes posterolateral infiltration of tumor beyond the pharyngobasilar fascia.

From Fleming I, Cooper J, Henson D, et al (eds): Manual for Staging of Cancer, 5th ed. American Joint Committee on Cancer. Philadelphia, Lippincott-Raven, 1997.

tebral space. Involvement of the prevertebral muscles is not uncommon and is best assessed by T2-weighted or enhanced MRI (see Fig. 19-14B and C). In late-stage disease, vertebral body destruction and spinal canal invasion occur at times.^{30, 130}

4. **Superior spread** results in skull base erosion and/or intracranial tumor extension, most commonly into the middle cranial fossa.²⁹ Skull base erosion occurs in up to one third of patients,²² whereas the frequency of detectable intracranial spread varies from 12% on CT scans up to 31% on MR images.^{29, 146} The most common route of intracranial spread is through the foramen ovale,^{27, 29, 30, 166} either via perineural mandibular nerve infiltration (see earlier) or by direct tumor extension into the foramen.¹¹⁹ Other less common routes include:

- Extension into the foramen lacerum, where the tumor encases the internal carotid artery, which leads it into the cavernous sinus, putting the III, IV, and VI nerves as well as the ophthalmic and maxillary divisions of the trigeminal nerves at risk of involvement.^{29, 30, 119}
- Direct destruction of the skull base (Fig. 19-17), commonly at the sites of muscular attachments, particularly the levator and tensor veli palatini.^{29, 100, 119}
- Direct invasion of the sphenoid sinus.²⁹

Intracranial extension into the posterior cranial fossa may also occur through the jugular foramen along the neurovascular bundle^{23, 108, 112} or through the foramen

Figure 19-15. Intracranial extension of nasopharyngeal carcinoma through the foramen ovale. The following images demonstrate a common route of intracranial extension of nasopharyngeal carcinoma through the foramina ovale while the skull base is intact. Such tumor extension occurs along the mandibular division of the trigeminal nerve and indicates that the tumor has already violated the masticator space.

A, Postcontrast coronal CT scan shows a mildly enhancing, right-sided soft tissue mass lesion (M), responsible for the asymmetry of the nasopharyngeal airway and extending intracranially, as evidenced by (1) the presence of a small parasellar enhancing soft tissue component (white arrow) obliterating the normal cerebrospinal fluid density of Meckel's cave and (2) widening of the right-sided foramen ovale (black arrow).

B, Postgadolinium-enhanced, coronal fat-suppressed, T1-weighted MR image of another patient shows an intensely enhancing, left-sided parapharyngeal and masticator space mass lesion that extends intracranially through the widened ipsilateral foramen ovale (double arrow) to attain an extra-axial location within the middle cranial fossa, obliterating Meckel's cave and elevating the left temporal lobe of the brain. The white arrow indicates a normal Meckel's cave.

Figure 19-16. Atrophy of muscles of mastication. Enhanced axial CT scan at the level of the nasopharynx (A) and axial T2-weighted MRI scan at the level of the oropharynx (B) demonstrate atrophy of the right and left masticator spaces, respectively, with consequent abundance of intermuscular fat planes.

magnum, but it is usually associated with gross bone destruction.²⁷ Indirect intracranial access has also been described through the foramen rotundum^{20, 24, 27, 125} and superior orbital fissure (see later).³⁰ A knowledge of the routes of intracranial spread of nasopharyngeal carcinoma is important in order to understand that bone erosion may not always be present. Indeed, the first sign of intracranial infiltration may be a mere dural thickening, along the floor of the middle cranial fossa,³⁰

that is best appreciated on contrast-enhanced coronal MR images.

5. *Inferior spread* may occur, often submucosally, and may be clinically occult down to the oropharynx, thereby increasing the T classification from stage T1 to stage T2. The tough pharyngobasilar fascia forms a moderately resistant barrier to tumor outgrowth, and such spread may be indicated by asymmetry of the PMS below the level of the hard palate or at the level of C1-C2.^{30, 108, 119}

Figure 19-17. Intracranial extension of nasopharyngeal carcinoma through skull base erosion. Coronal nonenhanced, T1-weighted MRI scan demonstrates an intermediate-signal-intensity soft tissue mass infiltrating the skull base on the left side and extending into the epidural space underneath the left temporal lobe of the brain. The ipsilateral Meckel's cave is compressed yet patent (see Fig. 19-15), suggesting that intracranial extension in this case has not occurred through the foramen ovale.

6. *Anterior spread* occurs into the posterior aspect of the nasal cavity from which the tumor may extend through the sphenopalatine foramen into the pterygopalatine fossa.³⁰ Once within the latter, perineural infiltration of the maxillary division of the trigeminal nerve is a potential route for intracranial extension through the foramen rotundum.²⁰ Uncommonly, further spread from the pterygopalatine fossa may occur through the inferior orbital fissure into the orbit, then through the superior orbital fissure into the cavernous sinus and middle cranial fossa. Invasion of the maxillary antrum and posterior ethmoids is also uncommon.^{30, 119} Obliteration of the normal fat within the pterygopalatine fossa on CT and MRI is a sign of its infiltration.^{32, 44}

Evaluation of follow-up scans after radiotherapy is one of the most challenging parts of the radiologic work-up of nasopharyngeal carcinoma. The clinician expects the radiologist to differentiate residual or recurrent tumor from postirradiation granulation tissue, because endoscopy that is already hampered by radiation-induced mucositis is not successful in detecting deep recurrence. Furthermore, biopsy needs to be guided to areas under suspicion and is somewhat limited by the poor capacity of tissues to recover.¹²⁵

Such evaluation is primarily the function of MRI because the CT attenuation of tumor and fibrous tissue are similar.¹²⁵ On MR images, mature scar tissue (formed of dehydrated hypocellular collagen) does not enhance with contrast and exhibits dark signal on T2-weighted images, an appearance that is readily distinguishable from tumor tissue.^{30, 125, 130} Yet immature scar (formed of well-hydrated hypercellular granulation tissue) cannot be differentiated from recurrent tumor on the basis of MR signal characteristics, because both show contrast enhancement and intermediate to high T2-weighted signal.^{30, 99, 125} In the latter case, the following measures may facilitate the diagnosis:

1. Ideally, a postradiotherapy baseline MRI is performed for comparison with future studies. This should be delayed for 3 to 4 months after completion of radiotherapy to allow for total resolution of slowly regressing tumors and acute postirradiation reactive changes (including thickening of the posterior pharyngeal wall and retropharyngeal edema). Progressively growing masses or tissue thickening should be deemed a recurrent tumor. Unchanging lesions do not exclude the possibility of tumor recurrence, whereas a regressive change points to a resolving postirradiation reaction or a contracting scar.^{119, 125, 148}
2. When previous scans are unavailable, detection of an obviously positive lymph node is a reliable sign of recurrence.¹¹⁹ Otherwise, studying the lesion's morphology may be helpful. It has been proposed that a recurrent tumor usually presents as a lobulated lump with mass effect, whereas postirradiation changes are usually a more diffuse process, giving rise to nasopharyngeal asymmetry with straight margins.²⁵ These criteria, however, should be considered suggestive and should not be regarded as the sole determinant of tumor recurrence.
3. When feasible, some techniques can be used to measure the metabolic activity of the mass in question, thus distinguishing a recurrent tumor by its high metabolic

rate from postirradiation scar tissue. These techniques include positron emission tomography (PET) with 18-fluorodeoxyglucose (FDG), thallium 201 scanning, and MR spectroscopy.^{54, 79, 117-119}

Finally, it is worth noting that meningeal infiltration, particularly in the posterior cranial fossa, may be the only manifestation of tumor recurrence without a detectable nasopharyngeal mass (due to submucosal spread). This occurs through the jugular foramen or the foramen magnum, each an uncommon route of spread in pretreatment patients. Thus, the basal meninges, the jugular foramen, and the foramen magnum as well as the internal acoustic meatus should always be scrutinized for occult recurrence. The pattern of flow in the jugular bulb, often giving rise to an intermediate to high T1-weighted signal and postcontrast enhancement, may complicate the evaluation of tumor recurrence within the jugular foramen. T2-weighted images and MR angiography are valuable in such cases.²⁷

Oropharyngeal Carcinoma. As in the nasopharynx, squamous cell carcinomas constitute the vast majority (90%) of all malignant neoplasms involving the oropharynx.^{85, 108} Again, most of these are poorly differentiated carcinomas.⁸ Predisposing factors for oropharyngeal squamous cell carcinoma are tobacco, alcohol, and syphilis.^{108, 119} Carcinoma arises most commonly from the palatine tonsils and base of the tongue.¹⁸⁴ Less common sites are the faucial arches, soft palate, and the posterior pharyngeal wall. Spread pattern and lymphatic drainage vary according to the site of origin,¹¹⁹ yet the overall incidence of cervical metastatic lymphadenopathy is 50% to 70%, which renders the prognosis unfavorable in most cases.⁸

Clinical Presentation. Patients often present with a sore throat, localized pain, referred ipsilateral otalgia, dysphagia, trismus, or a neck mass. Examination usually reveals a friable ulcerating mass.^{55, 152}

Imaging Features

Carcinoma of the Base of the Tongue (Fig. 19-18). Base of tongue carcinoma often arises on one side behind the circumvallate papillae, and it is more aggressive and infiltrative than that involving the anterior two thirds of the tongue. As a result of the rich lymphatic network in this region, up to 75% of patients have lymph node metastases at initial diagnosis, primarily involving the internal jugular and, to a lesser extent, the spinal accessory nodes. Submandibular nodes are also involved when the tumor infiltrates the mouth floor.¹¹⁹

Unfortunately, differentiation between carcinoma and normal lymphoid tissue (lingual tonsil) at the tongue base may be difficult on the basis of tissue morphology, CT density, and MR signal characteristics. Lingual tonsils may be large, lobular, and asymmetrical. Moreover, the T2-weighted MR signal as well as the enhancement patterns on MRI and CT are similar for both carcinoma and lymphoid tissue. The usual infiltrative nature, coupled with the high incidence of metastatic lymphadenopathy associated with carcinoma, confirms the diagnosis. Otherwise, a deep endoscopic biopsy is needed.^{8, 56, 62, 81}

Tongue base carcinoma may extend *anteriorly* to infiltrate the mobile portion of the tongue and the floor of

Figure 19-18. Squamous cell carcinoma of the tongue base. A, Contrast axial CT scan demonstrates a large, mildly enhanced mass lesion (M) involving the left root of the tongue, obliterating the normal fat plane between the pharynx and the medial pterygoid muscle, and extending posteriorly to infiltrate the anterior tonsillar pillar (palatoglossus muscle). B, Section at the level of floor of mouth in the same patient shows the tongue base mass to be violating the left sublingual space (harboring the left neurovascular bundle of the tongue) and infiltrating the ipsilateral genioglossus/geniohyoid muscles, yet stopping short of the midline.

the mouth; *laterally* to involve the pterygoid muscles and mandible; *superiorly* into the tonsillar fossa and soft palate; and *inferiorly* to fill the vallecula and to invade the preepiglottic space, the epiglottis, or the hypopharynx.⁸

Carcinoma of the Palatine Tonsils and Faucial Arches (Figs. 19-19 and 19-20). This carcinoma may arise from the mucosa lining the tonsillar bed, remnants of the palatine tonsils, and the anterior or, rarely, the posterior tonsillar pillar.¹¹⁹ Of these patients, 76% have clinically positive lymph node metastases occurring primarily in the jugulodigastric group. Spinal accessory as well as submandibular and retropharyngeal nodes may also be involved.^{8, 56, 119}

The tumor forms a bulging mass that thickens one side of the oropharynx from the soft palate to the hyoid bone.¹⁰⁸ Spread may occur *laterally* to invade the superior constrictor muscle into the parapharyngeal then the masticator space, with the potential risk of extension to the skull base (see “Nasopharyngeal Carcinoma”). Posterolateral extension into the retrostyloid PPS may lead to encasement of the internal carotid artery.¹⁸⁵ *Inferiorly*, the tumor may spread to the glossotonsillar sulcus, base of the tongue, and mouth floor, while *superiorly* it may infiltrate the soft palate and nasopharynx.⁸ It may be difficult to differentiate oropharyngeal tumors spreading up to the nasopharynx and vice versa. However, oropharyngeal tumors extending upward tend to invade the ipsilateral nasopharynx and masticator space in contrast to nasopharyngeal tumors, which tend to infiltrate the oropharynx in a diffuse fashion.¹¹⁹

Although the tonsillar regions may normally appear asymmetrical, they should be regarded with suspicion whenever they are associated with obliteration of the PPS or cervical lymphadenopathy.^{56, 123}

Carcinoma of the Soft Palate. The soft palate is associated

Figure 19-19. Squamous cell carcinoma of the left palatine tonsil has spared the parapharyngeal space. Axial CT scan obtained during bolus intravenous contrast administration reveals a rather ill-defined, mildly enhancing soft tissue mass centered on the left tonsillar fossa and extending along the anterior tonsillar pillar (palatoglossus muscle) into the soft palate and tongue base. Extension along the posterior pillar (palatopharyngeus muscle) into the posterior pharyngeal wall is also noted. The loss of definition of prevertebral fat plane on the left side suggests perivertebral space invasion yet may be due to mere compression. The parapharyngeal space is intact.

Figure 19–20. Squamous cell carcinoma of the right palatine tonsil has infiltrated the parapharyngeal space. Enhanced axial CT scan at the level of the oropharynx shows a well-defined intensely enhancing mass lesion involving the right tonsillar region, with central nonenhancing areas suggestive of tumor necrosis. The tumor infiltrates (1) the anterior tonsillar pillar into the right tongue base; (2) the posterior tonsillar pillar into the posterior pharyngeal wall, with possible involvement of the perivertebral space; (3) the prestyloid and poststyloid parapharyngeal spaces, where it abuts yet incompletely encases the internal carotid artery; and (4) the masticator space, where the tumor is seen as inseparable from the medial pterygoid muscle. Given such lateral extension, perineural spread along the mandibular nerve (V3) intracranially should be of concern.

with the best prognosis of all oropharyngeal carcinomas. The tumor usually arises on the oral side of the palate. Metastatic cervical lymphadenopathy is seen in 60% of patients at presentation; however, the incidence is far less (8%) for tumors less than 2 cm in diameter (stage T1). The high internal jugular and subdiaphragmatic nodes are first involved, followed by the lower internal jugular or retropharyngeal nodes.¹¹⁹

The tumor usually spreads first to the tonsillar pillars and hard palate. Other potential pathways include *lateral* infiltration along the tensor and levator veli palatini muscles into the PPS and up the skull base. *Superior* spread occurs to the nasopharynx or through the greater and lesser palatine foramina into the pterygopalatine fossa, then into the cavernous sinus.¹¹⁹ Palatine tumors are best evaluated by sagittal and coronal T1-weighted MRI. A tumor shows up as low signal in contrast to the normal bright T1-weighted signal of the palate caused by mucous glands and fat.¹¹⁹

Carcinoma of the Posterior Oropharyngeal Wall. Fortunately, this carcinoma is rare, as it carries the worst prognosis among all oral and oropharyngeal carcinomas.^{8, 56, 108} Arising in a silent area, the tumor is usually advanced at presentation. It tends to creep submucosally to infiltrate

the adjacent oropharyngeal sites, the nasopharynx, and the hypopharynx. Thus, the tumor may be relatively superficial yet extensive. Spreading *posterolaterally*, it may encase the carotid artery at an early stage. *Posteriorly*, it infiltrates the RPS, obliterating its fat stripe, but the prevertebral fascia is breached only at a later stage. Sagittal and axial postcontrast T1-weighted MRI best demonstrates this tumor, which may consist merely of subtle mucosal thickening.^{56, 108, 152}

Role of Imaging

The primary roles of the radiologist in evaluating oropharyngeal carcinoma are to:

1. Provide tumor staging.
2. Relay specific information to the surgeon regarding the involvement of some key anatomic structures that are crucial to planning the treatment strategy.
3. Assess post-therapeutic tumor recurrence.

The UICC/AJCC TNM classification of oropharyngeal carcinoma is presented in Table 19–3.

A problem-oriented radiologic assessment of oropharyngeal carcinoma should include specific comments on issues having a direct effect on the type and extent of subsequent surgery. These can be detailed as follows.

Invasion of Deep Fascial Spaces, Perineural Infiltration, and Skull Base or Intracranial Extension. As described earlier, oropharyngeal carcinomas can spread to invade the various fascial spaces about the pharynx (see Figs. 19–19 and 19–20). Perineural infiltration occurs primarily along the mandibular and maxillary divisions of the trigeminal nerve up to the skull base and intracranially.

Table 19–3. UICC/AJCC Tumor-Node-Metastasis (TNM) Classification of Oropharyngeal Carcinoma

T Staging	
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not greater than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4	Tumor invading adjacent structures (including bone [mandible, maxilla, hard plate], soft tissues of neck, deep muscles of tongue, larynx)
N Staging	
N0	No lymph node involvement
N1	Ipsilateral lymph nodes 3 cm or less
N2	
N2a	Ipsilateral lymph node greater than 3 cm, but not more than 6 cm
N2b	Multiple ipsilateral lymph nodes, but none greater than 6 cm
N2c	Bilateral or contralateral lymph nodes, but none greater than 6 cm
N3	Lymph nodes greater than 6 cm
M Staging	
M0	No distant metastases
M1	Distant metastases are present

AJCC, American Joint Committee on Cancer; UICC, International Union Against Cancer.

Data from Beahrs OH, et al (eds): *Manual for Staging of Cancer*, 4th ed. Philadelphia, JB Lippincott, 1992; and Leslie A et al: *J Comput Assist Tomogr* 23: 43–49, 1999.⁸⁶

Direct imaging signs of perineural spread (see Fig. 19-15) include:

1. Thickening and enhancement of the effected nerves (with attention also paid to possible skip lesions).
2. Abnormal enhancement in Meckel's cave.
3. Lateral bulging of the cavernous sinus dural membrane.

Indirect signs include:

1. Foraminal enlargement on CT (see Fig. 19-15A).
2. Atrophy of muscles of mastication (in mandibular nerve infiltration) (see Fig. 19-16).
3. Obliteration of the normal fat plane in the pterygopalatine fossa (in maxillary nerve infiltration).^{41, 82, 184}

Detection of subtle cortical skull base erosions requires coronal CT scanning, whereas MRI best assesses marrow infiltration. Intracranial extension may be first detected as abnormal meningeal thickening and enhancement. Again, this may be seen without skull base erosion.

Reporting such tumor extension changes the management of tonsillar and soft palate carcinoma from wide local excision through an intraoral approach to a more extensive surgery, depending on the structures infiltrated. At many institutions, imaging evidence of bulky tumor abutting the skull base precludes surgery.¹¹⁵

Preepiglottic Fat Infiltration. The preepiglottic space consists of the fat filling the area anterior to the epiglottis and posterior to the hyoid bone and thyrohyoid membrane. The site is best seen on sagittal T1-weighted MR images as a bright stripe (see Fig. 19-4). On axial scans, it appears as a C-shaped area of bright T1-weighted signal on MRI and low attenuation on CT.^{8, 65}

The preepiglottic space may be invaded by carcinoma of the tongue base (and, less commonly, by carcinoma of the piriform sinus). Infiltration is seen as soft tissue replacement of the normal fat content on either MRI or CT.^{8, 65}

A correct diagnosis is critical because preepiglottic invasion implies extension of surgery to include partial (supraglottic) or even total laryngectomy in combination with tongue base surgery. The consequent high morbidity and impairment of both swallowing and speaking adversely affect the patient's life quality.^{9, 184} Peritumoral edema, adjacent inflammation, and partial-volume effect on CT may mimic preepiglottic fat infiltration and should be always excluded.¹²⁰

Bilateral or Deep Tongue Base Invasion. Carcinoma originating primarily from the tongue base or extending to it from other oropharyngeal sites may spread across the midline or invade deeply into the floor of the mouth to involve the neurovascular bundle of the tongue (see Fig. 19-18B). The latter, consisting of the lingual artery as well as the lingual, glossopharyngeal (IX), and hypoglossal (XII) nerves, runs along the sublingual space on either side of the hyoglossus muscle to supply the tongue from posterior to anterior.^{121, 184}

The precise tumor extent can be depicted on postcontrast and T2-weighted MR images. One may also assess its relationship to the neurovascular bundle on postcontrast CT by locating the enhancing lingual vessels between the hyoglossus and genioglossus muscles on each side of the floor of the mouth.¹²¹

Accurate detection of such tumor extension has an important impact on the subsequent surgical procedure. That is, if one lingual neurovascular bundle can be preserved, partial glossectomy would be performed and the patient would still be able to function well in regard to both swallowing and speaking. For tumors that cross the midline and violate the contralateral lingual neurovascular bundle, treatment options include either total glossectomy (with lifelong feeding gastrotomy) or radiation therapy and chemotherapy.^{115, 184}

Encasement of the Internal Carotid Artery. This situation may occur from extension of oropharyngeal carcinoma into the retrostyloid PPS. Some suggest that when the tumor wraps more than 270 degrees of the arterial circumference on axial scans, it is unlikely to be resected without sacrificing the artery.¹¹⁰ At many institutions, surgery is precluded when imaging studies confirm the presence of internal carotid artery encasement.¹¹⁵

Bone Invasion

Mandibular Invasion. Advanced oropharyngeal carcinoma may extend to invade the mandible. Thin-section CT best depicts subtle cortical erosion, whereas MRI is best suited for detecting marrow invasion. Infiltrated areas of bone marrow appear dark on T1-weighted images, bright on T2-weighted images, and enhanced in postcontrast studies. Before the bone marrow is classified as "infiltrated," it is important to exclude other conditions demonstrating the same MR signal behavior, such as radiation fibrosis, osteoradionecrosis, osteomyelitis, and periodontal disease.^{34, 155, 184}

From a management perspective, tumors abutting the periosteum, but not fixed to it, are resected with periosteum for margin control. Tumors invading the periosteum or the cortex are removed with the cortex; for tumors infiltrating the mandibular marrow, resection of that segment of the mandible may be required.^{8, 34, 184}

Maxillary Invasion. The maxilla may be invaded *directly*, by carcinoma of the soft palate, or *indirectly*, by tonsillar carcinoma invading the retromolar trigone, then the maxilla.¹⁸⁴ Coronal thin-section CT best demonstrates subtle maxillary erosions. When the maxilla is involved, management reverts from wide local excision to resection through a partial maxillectomy.⁸

Prevertebral Muscle Invasion. Advanced cases of pharyngeal carcinoma, particularly those arising in the posterior pharyngeal wall, may invade the prevertebral muscles. Findings such as obliteration of the retropharyngeal fat stripe, irregular muscle contour, bright T2-weighted muscle signal, or postcontrast muscle enhancement on MRI or CT (see Figs. 19-19 and 19-20) should motivate the radiologist to report possible prevertebral muscle invasion. The definite extent, however, is determined by surgical evaluation, since these imaging findings may also be due to peritumoral edema without actual muscle invasion. When the tumor is proven to be fixed, it is deemed irresectable.^{8, 94, 184}

Assessment of post-therapeutic oropharyngeal tumor recurrence is often difficult because of the similar imaging appearance of recurrent tumor and post-treatment changes.^{72, 167} Because oropharyngeal cancer is primarily a surgical disease, tumor resection—and sometimes the

application of reconstructive procedures (e.g., myocutaneous or free flaps)—often further complicates interpretation by distorting the local anatomy.

As discussed earlier (see “Nasopharyngeal Carcinoma”), the optimal practice is to compare scans with a baseline post-treatment study. Otherwise, the detection of an obvious mass that is compressing rather than retracting the adjacent tissues or obvious lymphadenopathy will point to tumor recurrence.¹¹⁹

Non-Hodgkin's Lymphoma

Pharyngeal non-Hodgkin's lymphoma (NHL) arises from the rich extranodal lymphoid tissue of the PMS, the tongue base, or the palate.^{65, 184} Generally, 60% of cases of NHL arises in extranodal lymphoid tissue; of these, 60% occur in the head and neck.^{119, 182}

Clinical Presentation. Patients are usually older men presenting when having localized nasopharyngeal or oropharyngeal disease, with symptoms indistinguishable from those of squamous cell carcinoma arising at the same site.¹¹⁹ However, patients may present with systemic manifestations that point to the diagnosis. These include fever, malaise, weight loss, hepatosplenomegaly, and distant lymphadenopathy.⁶⁵ Distant lymphadenopathy is present in 80% of patients with primary extranodal NHL.¹¹⁹

Imaging Features. The imaging features of NHL of the PMS may be identical to those of the more common squamous cell carcinoma on both CT and MRI. Although lymphoma tends to grow in a circumferential fashion, forming a diffuse, bulky, non-necrotic, superficial mass without early invasion of the PPS,¹³³ large lesions may invade the deep neck spaces, spread perineurally, and invade the skull base in a pattern similar to that of squamous cell carcinoma.¹¹⁹ Superficial lymphomas primarily involving the tongue base or palatine tonsils may be also indistinguishable from benign lymphoid hyperplasia.¹⁸⁴

The diagnosis of NHL is suggested when the following associations are present:

- Large non-necrotic lymph nodes in atypical drainage areas
- Extranodal, extralymphatic lesions⁶⁵
- Clinical systemic manifestations

Malignancy of the Minor Salivary Glands

The minor salivary glands are the least common site of PMS malignancy. The tumor arises from the minor salivary glands in the submucosa of the nasopharynx and tongue base, yet its most common site is the soft palate. Generally, 50% of minor salivary gland tumors are malignant.¹¹⁹ A spectrum of histologic types exists, with adenoid cystic carcinoma the most frequent, followed by mucoepidermoid carcinoma and malignant mixed tumors.^{26, 28}

Clinical Presentation. Tumors usually occur in adults with no sex predilection.¹¹⁹ Symptoms are nonspecific⁶⁵ and depend on the site of origin of the tumor.

Imaging Features. The tumor appears as a soft tissue mass in the PMS that is indistinguishable on both CT and

MRI from squamous cell carcinoma or NHL. Biopsy is required for the definitive diagnosis.

Among all malignant nasopharyngeal and oropharyngeal neoplasms, adenoid cystic carcinoma is associated with the highest incidence of perineural spread.^{37, 41, 82, 184} Such spread is diagnosed histologically in about 50% of adenoid cystic carcinomas, and when the diagnosis is missed at initial evaluation, treatment failure may result.¹¹⁹ The direct and indirect imaging signs of perineural tumor spread have been described earlier (see “Oropharyngeal Carcinoma”).

Nasopharyngeal Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant mesenchymal tumor that occurs primarily in children. It can arise anywhere in the body, with the head and neck the most common sites of origin (28% to 36%), followed by the urinary bladder and then the extremities.⁴² Within the head and neck, the orbit and the nasopharynx are the most commonly involved areas. The tumor arises from the nasopharyngeal muscles, located within the PMS, and is associated with metastatic lymphadenopathy in 50% of cases. Distant metastases occur in the lung and bone.⁴²

Clinical Presentation. The peak age of incidence is 2 to 5 years, and boys are more susceptible than girls (2:1). The usual presenting symptoms are rhinorrhea, sore throat, and serous otitis media. Skull base invasion is common, giving rise to cranial nerve palsies.^{42, 119}

Imaging Features. The imaging appearance of rhabdomyosarcoma is basically that of a malignant nasopharyngeal growth in a child. The diagnosis is suggested on basis of the patient's age rather than a characteristic radiological appearance.

The tumor appears as a bulky nasopharyngeal soft tissue mass that commonly extends intracranially through both destruction of the skull base and widening of the basal foramina and fissures. CT shows an isodense mass to the brain, whereas MRI shows the tumor to be isointense on T1-weighted images and hyperintense on T2-weighted images.⁴² Postcontrast studies show a variable amount of enhancement. The same imaging features may be seen in children in cases of neuroblastoma and rhabdoid tumor.¹¹⁹

Lesions of the Retropharyngeal Space

Pseudotumors

The clinical appearance of an RPS mass may result from:

1. A tortuous internal carotid artery that extends medially and results in a bulge in the posterior pharyngeal wall.
2. Retropharyngeal hematoma.
3. Edema due to jugular vein or lymphatic obstruction. Edema of the RPS most commonly involves both its suprahyoid and infrahyoid portions and demonstrates low-attenuation enlargement of the space.⁴⁵

Congenital Lesions

Hemangioma and Lymphangioma

Hemangioma and lymphangioma are usually infiltrative lesions that do not respect the fascial boundaries (i.e.,

“trans-spatial” diseases) and may extend into the RPS as a part of multiple space involvement.

On CT scans, hemangiomas appear as relatively dense lesions and typically demonstrate intense enhancement.¹⁴¹ On MR images, they display intermediate signal intensity on T1-weighted and intermediate-weighted images, with heterogeneous increased signal intensity on T2-weighted images.^{3, 52} Following gadolinium administration, enhancement is usually intense.^{3, 141} Areas of signal void from associated vascular structures may be identified but are much more common with high-flow lesions.³

Lymphangiomas typically appear on both CT and MRI as multiloculated, poorly circumscribed lesions.¹³⁸ They exhibit fluid attenuation and signal intensity, and they have imperceptible, nonenhancing rims.¹³⁸ Hemorrhage may occur into a lymphangioma and may manifest clinically as rapid enlargement of the lesion; this may be identified as an area of high attenuation on CT and bright signal on T1-weighted MRI.^{3, 138} Hemorrhage-fluid levels may also be seen.³

Congenital vascular anomalies are currently classified as follows^{122, 139}:

1. *True hemangiomas*. These often involute with age. Involuting hemangiomas show focal areas of bright T1-weighted signal resulting from fatty replacement.³ Hemangiomas may look identical to venous malformations unless the venous malformation contains phleboliths.³
2. *Vascular malformations* (arterial, capillary, venous, lymphatic, and combined). These anomalies remain stable or slowly grow with the patient. Patients with these lesions typically require some form of therapy when cosmetic disfigurement, bleeding, or functional impairment is present.⁹¹

From a therapeutic perspective, the most important issue is to classify these lesions as *low-flow* vascular malformations, which are often successfully treated with percutaneous sclerotherapy,⁶⁰ and as *high-flow* vascular malformations, which are often treated with transarterial embolization.^{91, 183} T2-weighted MRI elegantly show the difference between these categories; low-flow lesions appear predominantly bright, and high-flow lesions appear predominantly signal void.^{60, 91, 183}

Inflammatory Conditions

Retropharyngeal Infections

Infection of the RPS is uncommon in adults, in whom it is most often due to direct posterior pharyngeal wall trauma as may occur during endoscopy or attempted nasogastric tube insertion.¹⁶⁴ This decreased incidence is most likely related to atrophy of the retropharyngeal lymph node chains following puberty.^{132, 164} Most commonly affected are patients 4 years of age or younger, in whom pharyngitis or infection of the adenoids or faucial tonsils (generally with streptococci or staphylococci) spreads to the retropharyngeal lymph node chains.

Typically, RPS infections progress in four successive phases and can be stopped at any stage by appropriate treatment:

1. *Reactive lymphadenopathy*. This phase represents the first response of the retropharyngeal lymph nodes to

spread of infection. The nodes react by hyperplasia without disruption of their internal architecture.

2. *Suppurative lymphadenitis*. The infected nodes suppurate, with consequent development of an intranodal abscess.¹⁴⁵
3. *Retropharyngeal cellulitis or abscess*. Early spread of the organism outside an affected lymph node may result in cellulitis, causing the tissues to swell without focal fluid collection.⁶⁵ When the enlarged suppurated nodes eventually rupture into the RPS, an abscess is formed. The abscess typically starts at the location of the lateral retropharyngeal lymph node chains lateral to the midline and above the level of the hyoid bone.¹⁷⁹ Infection then spreads to involve the entire RPS from side to side.⁴⁵
4. *Complicated retropharyngeal abscess*. When untreated, a retropharyngeal abscess can further spread locally into adjacent neck spaces, track downward into the superior mediastinum, or penetrate the alar fascia into the danger space, where it may spread down to the level of the diaphragm.¹³²

Clinical Presentation. Patients present with swelling adjacent to the soft palate, which may be displaced anteriorly; fever; sore throat; dysphagia; mild to moderate neck stiffness; and occasionally a muffled voice. Breathing may become strained or noisy if the airway becomes compromised.¹⁷⁹

Imaging Features

Reactive Lymphadenopathy. At this phase, enlarged lateral retropharyngeal lymph nodes (>1 cm in diameter) can be seen, keeping the configuration of normal nodes (oval or kidney-shaped) and usually presenting a homogenous texture.⁶⁵

Suppurative Lymphadenitis. Suppurated lymph nodes appear enlarged and demonstrate central low attenuation on CT or fluid signal intensity on MRI.^{45, 179} However, these central changes can also be seen in early liquefying nodes without complete suppuration. Frankly suppurated nodes can be identified by their enhancing rims (Figs. 19–21A) and by the associated edema of the RPS.⁶⁵

Retropharyngeal Cellulitis or Abscess. The most common finding in patients with infection of the RPS is that of cellulitis localized to the RPS at the level of the nasopharynx or oropharynx.⁴⁵ It is seen as diffuse thickening (>75% of anteroposterior diameter of vertebral body⁴²) and as enhancement of the retropharyngeal soft tissues (see Fig. 19–21).

When an abscess forms, it appears as an area of fluid collection margined by an enhancing rim, with possible air or air-fluid level seen within.⁴² As stated, it starts at the region of lateral retropharyngeal nodes (Fig. 19–22) but may spread to involve the entire RPS (see Fig. 19–21B), where it may attain a characteristic “bowtie” appearance.⁶⁵ Significant mass effect is often present,¹¹⁹ and the degree of pharyngeal airway compromise should always be sought.

It is also important to distinguish a true retropharyngeal abscess, which necessitates surgical drainage, from both suppurative adenitis (with surrounding edema) and cellulitis, because the latter two conditions may respond to conservative treatment without the need for intervention.^{65, 119}

Figure 19-21. Retropharyngeal infection in a 5-year-old boy presenting with left upper neck swelling.

A, Postcontrast CT scan reveals enlarged, left-sided lateral retropharyngeal lymph node (of Rouviere) (N), displaying central low attenuation and thick, enhancing margin, a picture consistent with suppurative lymphadenitis (intranodal abscess). The associated enlargement of palatine tonsils (arrowheads) indicates the source of infection. Note the integrity of the ipsilateral prestyloid parapharyngeal space (arrow).

B, Section at a lower level in the same patient shows low fluid attenuation casting the entire retropharyngeal space. The presence of a thin, enhancing rim marginating the collection suggests a retropharyngeal abscess (caused by rupture of another suppurated lymph node), rather than a mere associated edema, and necessitates the establishment of drainage. Note the bilateral posterior cervical space lymphadenopathy (arrows).

Complicated Retropharyngeal Abscess. The parapharyngeal fat may appear dense as a result of associated inflammation (see Fig. 19-21). When suppuration extends into this space, however, external drainage (rather than the transoral approach used with most retropharyngeal abscesses) is indicated.¹⁶⁴

Although axial CT usually demonstrates the full extent of retropharyngeal infection, sagittal MRI may occasionally

be helpful to better define the superoinferior extent of disease and associated displacement or compression of the pharynx, larynx, trachea, or esophagus.¹⁷⁹

Extension of RPS infection into the danger space cannot be differentiated from an RPS process unless abscess or cellulitis extends below the T2 to T6 vertebral level.

Benign Tumors

Retropharyngeal Lipoma

Benign tumors of the RPS are rare, although lipoma has been reported.⁴⁵ This tumor is readily identifiable on both CT and MRI as a retropharyngeal soft tissue mass with characteristic low CT density (-50 to -100 HU), bright T1 signal, and diminished signal on T2-weighted images.

Malignant Tumors

Malignant tumors of the RPS are much more common than benign tumors and are usually secondary to the following⁴⁵:

1. Direct extension of primary squamous cell carcinoma of the nasopharynx, posterior oropharyngeal wall, or hypopharynx.
2. Metastatic involvement of retropharyngeal lymph nodes.
 - a. Most commonly, from a nasopharyngeal primary squamous cell carcinoma but may also be seen with an oropharyngeal carcinoma.⁴⁵ Enlarged nodes may show central necrosis.
 - b. Metastases from other areas, such as thyroid carcinoma and malignant melanoma.⁴⁵ Involved nodes may present bright T1-weighted signals, in melanotic melanoma resulting from the paramagnetic effect and in thyroid carcinoma resulting from the high protein (thyroglobulin) content.⁶⁵

In addition, the retropharyngeal lymph node chains may

Figure 19-22. Retropharyngeal infection. Axial contrast-enhanced CT scan through the oropharynx demonstrates enhancing, thickened retropharyngeal soft tissue consistent with cellulitis (thin white arrow) and a low attenuation collection on the right suggesting abscess formation (thick white arrow) that causes significant airway compromise. Note the abscess starting at the region of the lateral retropharyngeal lymph node (of Rouviere). Associated inflammation results in increased attenuation of the prestyloid parapharyngeal fat on the right (black arrow).

be involved by non-Hodgkin's lymphoma, either as an initial site or as a part of a multiple chain involvement. Involved nodes initially appear unilateral and homogeneous, but later extranodal progression may cause the lymphomatous tissue to fill the entire RPS.⁶⁵

Lesions of the Prestyloid Parapharyngeal Space

Pseudotumor

Asymmetrical Pterygoid Venous Plexuses

Occasionally, the pterygoid venous plexus of one side (overlying the inner surface of the lateral pterygoid muscle) is larger than that of the other side. The vascular nature of this anatomic variant can be depicted by its racemose enhancement on postcontrast CT scans and on contrast-enhanced, fat-suppressed, axial T1-weighted MR images.⁶⁵

Congenital Lesions

Atypical (Parapharyngeal) Second Branchial Cleft Cyst

The lower face and neck are formed from six pairs of branchial arches. Between them lay five endodermal pharyngeal pouches on the inner aspect and five ectodermal clefts on the outer aspect.^{10, 16} The second pharyngeal pouch forms the tonsillar fossa and palatine tonsils, whereas the second branchial cleft (together with the third and fourth clefts) forms an ectoderm-lined tract, called the *cervical sinus*,⁶⁶ which is obliterated at a later stage of development.

Failure of the cervical sinus to become completely obliterated results in a second branchial cleft sinus, a fistula, or, more commonly, a cyst anywhere along a line from the oropharyngeal tonsillar fossa to the supraclavicular region of the neck.⁶⁶ Although the most common location for a second branchial cleft cyst is the submandibular space,³⁶ the cyst can atypically present in the PPS, arising from the parapharyngeal portion of the embryonal tract.⁶⁶

Clinical Presentation. Although congenital, these cysts most commonly present in young adults and are often precipitated by respiratory tract infection or trauma.⁶⁶ Small cysts are asymptomatic. Patients with a large cyst in the parapharyngeal location may present with parotid gland bulge, dysphagia, or vague neck discomfort.¹⁵ On examination, the posterolateral oropharyngeal wall appears to be bulging internally.⁶⁵

Imaging Features. In its atypical (parapharyngeal) location, the cyst appears on CT and MRI as a thin, smooth-walled structure of fluid attenuation or signal intensity extending from the deep margin of the palatine tonsil into the parapharyngeal fat toward the skull base.⁶⁵ Occasionally, T1 hyperintensity may result from high protein content or intracystic hemorrhage.¹⁵ When infected, the cyst wall may become thickened and irregular, and the surrounding fat planes may become obscured.⁶⁶

As mentioned, the most common site of a second branchial cleft cyst is within the submandibular space, characteristically displacing the submandibular gland anteriorly, the sternocleidomastoid muscle posterolaterally, and the carotid sheath posteromedially.³⁶ At this location, it is important to consider cystic metastasis of papillary thyroid

carcinoma in the differential diagnosis. An enhancing soft tissue nodule in cystic metastasis may provide a clue to the diagnosis.

Other cystic lesions of the submandibular space (but rarely giving the characteristic pattern of displacement of adjacent structures) include submandibular gland cysts, lymphangiomas, necrotic or cystic nerve sheath tumors, and epidermoid or dermoid cysts.⁶⁶

Inflammatory Conditions

Parapharyngeal Space Infection

Infection of the prestyloid compartment of the PPS most commonly arises from spread of peritonsillar abscesses, retrotonsillar vein thrombophlebitis, third molar extractions with violation of the pterygomandibular raphe, penetrating injury to the lateral pharyngeal wall, or extension of deep lobe parotid abscesses or as a complication of local anesthesia for tonsillectomy or dental surgery.^{164, 179} Inflammation may also spread from the submandibular glands, branchial cleft, or thyroglossal duct cysts or from temporal bone infections through petrous apex air cells.¹⁶⁴

Patterns of spread of inflammatory changes within the PPS and the adjacent spaces depend on individual differences in fascial anatomy that may arise from normal variation, previous trauma, surgery, infection, or radiation therapy.¹³² The virulence and antibiotic sensitivity of the invading organism, as well as the general health and immunologic status of the host, may also affect the spread of infection.¹³² Once inside the prestyloid PPS, infection can readily extend into the parotid, masticator, submandibular, or retrostyloid compartment of the PPS.¹⁶⁴

Clinical Presentation. Clinical presentation of the PPS and the adjacent spaces includes the sudden onset of fever and chills. Dysfunction of cranial nerves IX through XII or the sympathetic plexus may also occur with extension into the retrostyloid compartment, and trismus may occur with masticator space involvement. Painful swelling of the gingival tissues of the maxilla and of the cheek on the involved side may also be noted.¹⁷⁹ On clinical examination, a medial bulge of the lateral pharyngeal wall is commonly seen.^{164, 179}

Complications of PPS infection include erosion of the adjacent carotid artery with fatal hemorrhage or pseudoaneurysm formation as well as extension to the RPS with possible asphyxia or dysphagia from the resulting mass effect and inflammation.¹⁷⁹ Paranasal sinus and orbital involvement, intracranial extension, and osteomyelitis may also result.⁵²

Imaging Features. Imaging of the PPS and the adjacent spaces may be of great assistance in detecting complications of deep neck infections and determining the optimal timing and approach for surgical drainage.¹⁶⁴ Imaging is most useful when infection is complex, widespread, or difficult to assess clinically.⁵² On CT, cellulitis may present as a soft tissue mass with obliteration of adjacent fat planes. The mass is often ill defined, enhancing, and extending along fascial planes (Fig. 19–23) and into subcutaneous tissues.^{52, 179} Involved muscles may enhance and appear enlarged, and overlying subcutaneous tissues often demon-

Figure 19–23. Prestyloid compartment parapharyngeal space infection from spread of tonsillitis. Axial contrast-enhanced CT scan at the level of the oropharynx demonstrates enlargement of the right faucial tonsil with obliteration of the prestyloid parapharyngeal fat on the right. One small area of decreased attenuation is noted within the inflammatory process, which may represent a small abscess cavity (*black arrow*). Fat planes surrounding the contents of the retrostyloid compartment of the parapharyngeal space remain intact (*white arrow*).

strate linear or mottled increased attenuation beneath thickened skin.¹⁷⁹

Abscesses of the deep neck spaces, reported to represent up to 9% of masses within the PPS, often appear as unilocated or multiloculated cystic lesions with air or fluid attenuation centers. They may have somewhat irregular, enhancing walls or surrounding tissue edema and may conform to the surrounding fascial boundaries.^{103, 164, 179} Occasionally, pus formation is incomplete or may be delayed by antibiotic therapy, and an area of low attenuation on CT, suggesting an abscess cavity, may not yield pus on aspiration or exploration.¹⁷⁹

Although axial and coronal CT may determine the extent of disease and presence of complications, MRI often provides superior localization because of its multiplanar capabilities and better soft tissue contrast resolution. Inflammatory exudate is of low to intermediate signal intensity on T1-weighted images and is often isointense with adjacent muscle.¹⁷⁹ Both cellulitis and abscess cavities exhibit increased signal intensity on T2-weighted images.

Gadolinium contrast agents may help to differentiate abscess from cellulitis by demonstrating an enhancing abscess wall. Neither MRI nor CT findings can typically differentiate a bacterial from a granulomatous origin of inflammation.¹⁷⁹

Benign Tumors

Most prestyloid PPS tumors are benign. Of these, the majority are of salivary gland origin, with pleomorphic adenoma representing the most common histology.⁸⁴

Benign Mixed Salivary Gland Tumor (Pleomorphic Adenoma)

Salivary gland tumors in the prestyloid PPS commonly arise from the deep lobe of the parotid gland and extend

into the PPS through the stylomandibular tunnel.⁸⁴ However, salivary gland tumors can also arise primarily within the prestyloid compartment from congenital rests of salivary gland tissue.^{84, 162}

Clinical Presentation. The patient typically presents with a painless mass, since benign salivary gland tumors seldom result in other symptoms.⁶⁸

Imaging Features. The CT appearance of a benign salivary gland tumor is usually that of an ovoid soft tissue mass. When small, the tumor is typically homogeneous; when larger, it may show variable areas of low attenuation that represent sites of cystic degeneration or seromucinous collections. Focal areas of high attenuation representing calcification may also be present.¹⁶²

The MR appearance of a benign salivary gland tumor is that of a well-defined mass with low to intermediate signal intensity on T1-weighted and intermediate-weighted (long TR, short TE) images and intermediate increased signal on T2-weighted images (Fig. 19–24). Smaller lesions are typically homogeneous in appearance, whereas lesions greater than 2.5 cm in diameter are often heterogeneous on all pulse sequences and may have internal foci of low signal or signal void, corresponding to areas of calcification or fibrosis (see Fig. 19–24).¹⁶² Areas of high signal intensity on T1-weighted and intermediate-weighted MR images may also occur in larger tumors and correspond to areas of local hemorrhage.¹⁶² With the prevalence of such findings, mass heterogeneity is not a useful predictor of a benign versus a malignant neoplasm.¹⁶² The best predictors of a benign pleomorphic adenoma are the presence of dystrophic calcifications, best detected with CT, or a well-defined, highly lobulated tumor contour, best seen with MRI.¹⁶²

The site of origin of prestyloid compartment salivary neoplasms is of importance in the surgical management of these patients, because a lesion arising within the deep lobe of the parotid gland is usually treated with operative control of the facial nerve in order to prevent nerve damage, whereas a lesion totally confined to the prestyloid PPS without connection to the parotid gland may be treated with little concern for facial nerve injury.¹⁵⁹ At some institutions, a submandibular approach without control of the facial nerve is also used for deep lobe parotid masses when the tumor does not approach the stylomandibular tunnel.

For an accurate diagnosis of an extraparotid origin of a prestyloid parapharyngeal tumor, an intact fat plane between the posterolateral margin of the tumor and the deep portion of the parotid gland must be clearly demonstrated. Careful attention is necessary because this connection may be a very thin isthmus of tissue that is best detected on high-resolution, thin-section, axial T1-weighted MR images. When lesions are greater than 4 cm in diameter, the intervening fat plane may be obliterated by mass effect alone and distinguishing between intraparotid and extraparotid origin may be impossible (see Fig. 19–24).¹⁶² In such cases, the surgical approach for a tumor of parotid origin is often used in order to minimize the risk of facial nerve damage.^{159, 162}

Parapharyngeal Lipoma

Parapharyngeal lipomas are uncommon lesions that are readily identified by their characteristic low attenuation on

Figure 19-24. Pleomorphic adenoma.

A, Nonenhanced, T1-weighted axial image (TR = 500 msec, TE = 12 msec) demonstrates a well-defined mass of lower signal intensity than adjacent muscle, replacing the prestyloid parapharyngeal fat with minimal residual fat displaced medially (*straight white arrow*) and the internal carotid artery displaced posteriorly (*straight black arrow*). No intact fat plane can be demonstrated between the lesion and the deep lobe of the parotid gland (*open arrow*).

B, Intermediate-weighted (TR = 2500 msec, TE = 30 msec) coronal image demonstrates the mass as relatively homogeneous, of increased signal intensity relative to adjacent muscles and lymphoid tissue, and well defined. The oropharyngeal mucosa is displaced medially. The left medial pterygoid muscle is compressed and displaced superolaterally (*arrows*).

C, Contrast-enhanced, T1-weighted (TR = 500 msec, TE = 15 msec) sagittal image demonstrates marked heterogeneity of the mass, with multiple low-signal-intensity regions that may represent areas of calcification or fibrosis. Both sagittal and coronal images are useful in revealing the craniocaudal extent of the lesion, which fills most of the prestyloid parapharyngeal space (*arrows*). The mass is inseparable from the deep lobe of the parotid gland and must be considered as arising from the deep lobe for surgical planning. However, the deep lobe of the parotid gland has been compressed and displaced laterally, with no visible connection to the mass at surgery.

CT and by their characteristic signal intensity, which parallels that of fat on all MRI pulse sequences.

Malignant Tumors

Malignant tumors of the prestyloid compartment of the PPS are much less common than benign lesions. These tumors include malignancies of salivary gland origin (e.g., mucoepidermoid, adenoid cystic, and acinic cell carcinomas) along with direct invasion of malignancies of the adjacent spaces.^{156, 162} Differentiation from benign tumors may be difficult because approximately two thirds of salivary gland malignant tumors have smooth, well-defined margins.¹⁶² However, the presence of an irregular, ill-defined margin or infiltration of surrounding tissues may be

present, suggesting a more aggressive lesion. Unfortunately, an inflammatory reaction surrounding a benign tumor may occasionally result in a similar appearance.¹⁶¹

Lesions Arising Outside the Pharynx and Bulging into the Pharyngeal Airway

Antrochoanal Polyps

An antrochoanal polyp is a benign antral polyp that expands, widens the sinus ostium, and prolapses into the nasal cavity. When the polyp is large, it fills the ipsilateral nasal fossa and extends backward through the choana into

Figure 19–25. Basal cephalocele. Coronal nonenhanced CT scan shows a large midline, isodense nasopharyngeal soft tissue mass that is significantly compromising the airway in a child. The obvious associated midline skull base defect represents the persistent hypophyseal (craniopharyngeal) canal and suggests that the postnasal mass is actually a herniated pituitary gland. Note the consequent downward traction of the suprasellar cistern into the basal defect.

the nasopharynx. Occasionally, it becomes large enough to hang down into the oropharynx. Antrochoanal polyps represent 5% of all nasal polyps.^{42, 119}

Clinical Presentation. The patient is typically a teenager or a young adult. A history of allergy is present in 15% to 40% of cases, with an incidence of additional nasal polyps in 8%.^{42, 160}

Imaging Features. A large antrochoanal polyp appears as a smoothly outlined mass within the nasopharyngeal airway; it is continuous into the nasal cavity and maxillary antrum on one side. The maxillary ostium is widened, yet the sinus itself is not expanded. There is no bone erosion. Absence of bone erosion is a distinguishing feature from juvenile nasopharyngeal angiofibroma. An antrochoanal polyp typically presents as a homogenous, low-mucoid-attenuation (10 to 18 HU) mass on CT, but older lesions develop fibrous stroma, resulting in a higher attenuation. On MR images, these polyps display low to intermediate T1-weighted and T2-weighted signal intensity. Post-contrast studies show mucosal enhancement on the surface.^{42, 97, 133, 160}

Sphenchoanal Polyps

Sphenchoanal polyps are rare, with an etiology similar to that of antrochoanal polyps. They arise in the sphenoid sinus and extend through the sphenoid ostium and sphenomethmoidal recess into the nose, then backward through the choana into the nasopharynx. Identification of the sinus of origin (sphenoid and not maxillary) is important in order to determine the surgical approach.¹⁸¹

Persistent Hypophyseal (Craniopharyngeal) Canal

Persistent hypophyseal canal is a rare congenital defect of the skull base that is worthy of mention. The canal connects the pituitary fossa to the nasopharynx, allowing the pituitary gland to herniate downward into the nasopharyngeal

airway and to present as a midline nasal polyp that might cause significant airway obstruction in neonates.⁷⁴

Because acquired polyps are almost unknown in children younger than 2 years of age, it is necessary to interpret, with a high index of suspicion, midline nasal polyps in young children, particularly when the polyp is coupled with hypertelorism. In these cases, it is always best to ascertain that the sellar floor is completely intact and that the pituitary gland is normally located within its fossa. Coronal CT or MRI is best suited for such evaluation.⁷⁴ Picking up these rare cases is crucial in order to prevent inadvertent hypophysectomy and consequent panhypopituitarism.

Occasionally, a persistent hypophyseal canal may be wide enough to allow a large basal cephalocele to form in the postnasal space (Fig. 19–25).⁷⁴

Nasopharyngeal and Oropharyngeal Trauma

The suprahyoid portions of the pharynx (i.e., nasopharynx and oropharynx) are less vulnerable to trauma than the infrahyoid pharynx (hypopharynx) or the larynx¹¹⁹; most radiologically documented nasopharyngeal or oropharyngeal injuries are described in the literature as case reports.*

The clinicopathologic outcome and the imaging findings expected after trauma to this part of the pharynx, to a large extent, are dictated by the mechanisms of trauma. By convention, these are classified into *blunt* (closed) and *penetrating* (open) types.

Blunt Trauma

Blunt head and neck trauma, such as that caused by motor vehicle accidents, may result in the formation of retropharyngeal hematoma, a condition that may progress rapidly into a life-threatening airway obstruction.^{18, 45}

*See references 43, 75, 104, 106, 114, 129, 135, 137, 153, 157, 169, 170, and 175.

Once post-traumatic, prevertebral soft tissue fullness is seen on the emergency radiographs, the primary concern should be directed toward securing and maintaining the patient's airway,⁴³ followed by a CT scan to evaluate for potential cervical spine fractures. CT sections should start as high as the skull base to detect possible occipital condyle fractures¹⁰⁴ and should cover as low as the inferior extent of the hematoma, which may reach down to the mediastinum.

Retropharyngeal hematomas have also been reported following minor blunt trauma,⁴³ minor hyperextension injuries,¹²⁹ and airbag deployment in minor motor vehicle accidents.¹⁷⁰

Nontraumatic causes of retropharyngeal hematoma include anticoagulant therapy and complications of aneurysms, tumors, and infections.¹²⁹

Penetrating Trauma

Trauma leading to pharyngeal perforation may be accidental or iatrogenic. Accidental perforations usually involve the oropharynx and may be caused by foreign bodies,⁴⁵ fish bones,¹⁶⁹ gunshots,¹⁶² and direct injury by intraoral sharp objects, as when, for example, a child falls with a toothbrush in the mouth.¹³⁷ Iatrogenic perforations more commonly involve the nasopharynx and may complicate upper gastrointestinal endoscopy,¹⁷⁵ assisted ventilation,⁴⁵ neonatal pharyngeal suction catheters, and nasogastric or tracheal intubation during resuscitation of newborns.¹³⁵

Pharyngeal perforation may result in any or a combination of the following problems:

1. *Surgical emphysema.* Emphysema may be caused by air dissecting its way through the torn pharyngeal wall. Retropharyngeal free air is the most common sequela of perforation and is readily identified on CT. Occasionally, large amounts of interstitial air may cast multiple deep fascial spaces and may extend downward, giving rise to pneumomediastinum.^{45, 143, 157, 175}
2. *Retropharyngeal abscess.* Abscess occurs less often and is due to the spread of organisms from the oral bacterial flora. Uncontrolled infection may spread into the deep fascial planes, resulting in fascitis or parapharyngeal abscess¹¹⁹; may extend downward along the RPS to cause mediastinitis; and may even enter the danger space to reach down to the diaphragm.¹⁵⁷ The imaging features of retropharyngeal abscess have been described earlier.
3. *Vascular injury.* Internal carotid artery thrombosis and cerebral ischemia may complicate posterolateral oropharyngeal injury, particularly when a child falls with a sharp object in the mouth. Typically, the internal carotid artery is injured 1 to 3 cm above the common carotid bifurcation, where it is separated from the oropharyngeal airway only by the tonsil and the superior constrictor muscle. The patient classically presents after a lucid interval of occasionally more than 24 hours, with disturbed consciousness, hemiplegia, and possibly expressive aphasia if ischemia involves the dominant cerebral hemisphere.¹³⁷

Carotid artery thrombosis has also been reported following blunt intraoral¹¹⁴ and minor pharyngeal injuries.¹⁵³

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome is an episodic upper airway obstruction during sleep, most commonly occurring at the pharyngeal level.¹⁰² The condition may be considered, in part, a neuromuscular disorder. Normally, the neural output to the pharyngeal muscles decreases with the onset of sleep, thus reducing their tone. With inspiration, the negative pressure created in the upper airway has the potential to collapse the hypotonic pharyngeal wall if the pharyngeal airway is originally smaller or more compliant than normal.⁵⁷

Clinical Presentation. Obstructive sleep apnea is most common among obese males. The incidence also increases with age, snoring, tobacco and alcohol use, and the use of sedatives as well as with genetic and familial risk factors.¹⁰²

The repetitive episodes of apnea during sleep, lasting from 10 to more than 60 seconds,¹⁰² result in arterial oxygen desaturation and recurrent awakening, leading to the syndrome, which is characterized by daytime somnolence, morning headache, and poor concentration.^{57, 78} Other conditions that have been linked to the syndrome include gastroesophageal reflux, impotence, cardiac arrhythmias, hypertension, and increased risk of stroke and myocardial infarction.^{78, 102}

Role of Imaging. The diagnosis of obstructive sleep apnea is a clinical one that is supported by (1) overnight *polysomnography* (continuous recording of relevant physiologic changes during sleep) to determine the physiologic severity, and by (2) *transnasal fiberoptic endoscopy* to estimate the actual grade of airway narrowing.¹⁰²

With the emergence of new imaging technology, dynamic imaging of the pharynx in near real-time has become a reality, permitting the noninvasive assessment of functional pharyngeal abnormalities. Many reports have described the use of *ultrafast CT* (electron beam CT)^{12, 50, 51, 57, 163} and *MR fluoroscopy*^{78, 144, 150, 151, 168} for the dynamic evaluation of upper airways in these patients.

Ultrafast CT scanning utilizes an electron gun to produce a fast-moving electron beam that hits multiple detector rings in the gantry, permitting the simultaneous acquisition of multiple image sections. This results in a superior temporal resolution, and images can be obtained in as little as 50 to 100 msec.⁷¹ Other than its use of ionizing radiation, the disadvantage of selecting ultrafast CT in evaluating patients with obstructive sleep apnea is the inability to obtain primary images in the midsagittal plane.⁷⁸

The term *MR fluoroscopy* has been introduced with the development of numerous rapid gradient-echo sequences capable of acquiring MR images as fast as 0.3 to 7 seconds per frame.^{88, 93} Fluoroscopic MR imaging has been used for functional imaging of the upper airways utilizing GRASS (gradient-recalled acquisition in the steady state)^{78, 150, 151} and FLASH (fast low-angle shot) sequences.^{78, 168} Images are obtained in the sagittal and axial planes during quiet nasal respiration, simulation of snoring, and performance of the Müller maneuver (inspiratory effort with the mouth and nose closed).⁷⁸ Axial scans are obtained at the levels of the oropharynx and velopharynx (the lowest part of nasopharynx opposite the soft palate, which is one of the narrowest sites in patients experiencing obstructive sleep apnea).¹⁴

Two fundamental imaging abnormalities are sought in evaluation of these patients^{57, 78}:

1. Narrowing of the luminal cross-sectional area of the pharynx, as seen on axial images. The length of narrowing is determined on sagittal images.
2. Increased compliance of pharyngeal walls. The mobility of the uvula, tongue base, and posterior pharyngeal wall is assessed on sagittal images, whereas the mobility of the lateral pharyngeal walls is assessed on axial images.

Suprahyoid Neck Biopsy and Interventional MRI

Interventional MRI is the use of MR techniques to guide radiologic interventions, including both diagnostic and minimally invasive therapeutic procedures.

In areas of complex anatomy, the tissue contrast, spatial resolution, and multiplanar capabilities peculiar to MRI provide the obvious advantages for its use to guide interventional procedures. This is particularly true for sampling suprahyoid neck lesions,^{88, 92, 109} an endeavor in which CT guidance is limited by several factors, including the following:

1. The inability to maintain a confident localization of the vascular anatomy throughout the procedure.
2. The inability to go beyond a single imaging plane (usually axial).
3. The frequent improper definition of pharyngeal submucosal lesions on CT.

4. The beam-hardening artifacts inherent in CT at the skull base.

On the contrary, the major benefits of using MRI for procedure guidance in this region (Fig. 19–26) are as follows^{88, 92, 109}:

1. The ability to continuously visualize the internal carotid, vertebral, and major branches of the external carotid arteries during the entire needle insertion procedure. The high vascular conspicuity is due to flow-related enhancement effects inherent in the gradient-echo sequences used for procedure guidance.
2. The multiplanar imaging capabilities that ensure precise needle centralization along the axial as well as the craniocaudal dimensions of the lesion. In addition, imaging in any arbitrary plane allows the needle trajectory to be tailored according to the individual case.
3. The ability to guide needle insertion with continuous, near real-time imaging so that the needle can be redirected in order to avoid critical structures in a time-efficient manner.
4. The ability to shift between T1-weighted and T2-weighted contrast during the procedure to maximize lesion conspicuity. T2-weighted techniques also allow sampling of the non-necrotic regions of complex masses, thus increasing the diagnostic tissue yield.

An additional use of the interventional MRI techniques that form the basis for biopsy guidance is application of these methods for the monitoring of direct intralesional drug injection, including injection for sclerotherapy of vascular malformations. The same rapid image updates used

Figure 19–26. Interventional near-real-time, MR-guided suprahyoid neck biopsy. Images from continuous series obtained at 7 seconds per image with fast imaging with steady-state precession (FISP) sequence (TR = 18 msec, TE = 7 msec, 4 signal averages, flip angle = 90 degrees) obtained during guidance of needle insertion in a 68-year-old man with a C1-2 vertebral and prevertebral mass. A previous attempt at surgical transoral biopsy had been unsuccessful.

A, Image obtained early, during needle insertion, demonstrates the needle tip passing through the left parotid space. An ill-defined mass can be seen in the prevertebral space. High vascular conspicuity resulting from 2D Fourier transform technique allows ready visualization of flow-related enhancement within the internal carotid (arrowhead) and vertebral (curved arrow) arteries. The needle tip (straight arrow) can be interactively directed to avoid these major vascular structures.

B, The needle is redirected more anteriorly once it is safely beyond the internal carotid artery (ICA). The location of the needle's side notch is shown as an area of thinning of the distal needle tip (between arrowheads). Histologic examination revealed chronic osteomyelitis and cellulitis, and the offending organism was successfully isolated.

Figure 19-27. Interventional MRI suite setup for radiologic intervention has an open magnet design to provide easy patient access and a video camera sensor array (curved arrow) to detect the location and orientation of a hand-held probe (black arrow). The system automatically acquires continuous MR images based on the probe position and automatically updates display of four images on shielded liquid crystal diode monitor adjacent to the scanner (arrowhead). A computer mouse on the LCD console and foot pedals (not shown) allow the scanner to be operated by the radiologist throughout the procedure.

for interactive needle placement can be used to monitor the injection of sclerosing agents for the treatment of low-flow vascular malformations.⁹¹ The multiplanar images obtained with MRI allow the injection of alcohol or other sclerosing agents to be monitored during administration to ensure filling of the entire targeted portion of the malformation and to exclude extravasation or dissipation of the agent through venous egress.⁹¹

The accuracy and safety of MRI-guided procedures depend on proper needle visualization. Achieving this task requires a sound understanding of a number of user-defined imaging parameters as well as needle trajectory decisions, which are beyond the scope of this chapter.^{88, 90, 93, 109}

Three basic components combine to form the foundation of the modern interventional MRI suite:

1. The availability of an "open" magnet imaging system to facilitate the patient access necessary for performing the procedures (Fig. 19-27).
2. The application of new, fast gradient-echo pulse sequences that allow a wide range of tissue contrast in a time frame sufficient for device tracking (between 0.3 and 7 seconds per image), even at the low field strengths of open magnets and with the suboptimal coil position sometimes required to access the puncture site.^{35, 48, 93, 98, 109}
3. The ability to view images in near real-time at the scanner side through an in-room high resolution radio-frequency-shielded monitor (see Fig. 19-27).^{88, 93, 186}

With these three components, the entire procedure can be performed with the operator sitting next to the patient and without the need to remove the operator's hand from the interventional device at any time. This manner of intervention, analogous to an angiographic or sonographically guided procedure, is well suited to the skill set developed by radiologists during more conventional types of image-guided intervention.

Thyroid and Parathyroid Glands

Theodore C. Larson III, Michelle M. Smith,
Wui K. Chong, William H. Martin

Thyroid Gland

The shield-shaped thyroid gland is normally positioned anterior and lateral to the cricoid cartilage, although its position may be located more superiorly, anterior to the thyroid cartilage, or more inferiorly, anterior to the trachea. The thyroid contains two lobes, each with a superior and inferior pole; an isthmus; and, in 50% to 80% of patients, a pyramidal lobe that originates from the isthmus or the medial aspect of either lobe. The pyramidal lobe develops along the distal embryonic thyroglossal duct, which explains its location. Similarly, thyroid tissue may be ectopically located anywhere along its developmental migration track (i.e., as a lingual thyroid at the base of the tongue, within a vestigial thyroglossal duct cyst, or further caudally within the mediastinum) (Fig. 20-1).

The superficial location of a normally positioned thyroid gland makes imaging easily accomplished with ultrasonography. Using a 7.5- to 10-MHz linear-array transducer provides 2-mm spatial resolution, although penetration depth and range of view are somewhat curtailed. The normal thyroid gland is homogeneous and more echogenic than muscle but less echogenic than fat. The standard

examination provides transverse and longitudinal planar images with evaluation of regional cervical lymph nodes.

Ultrasonography is often the first modality used to image the thyroid gland because it is convenient, inexpensive, quick, and easy to perform. Ultrasonography readily identifies and distinguishes between cystic and solid lesions without using ionizing radiation, although thyroid disorders and diseases that are purely cystic are uncommon. Ultrasonography typically detects more thyroid masses than does computed tomography (CT), magnetic resonance imaging (MRI), or scintigraphy because of its greater spatial resolution. Limitations of ultrasonography include difficulties in evaluating ectopically located thyroid tissue, predicting the functional status of thyroid nodules, and surveying the neck for metastatic lymphadenopathy.

Radiopharmaceuticals used in evaluating the thyroid include technetium 99m-pertechnetate (^{99m}Tc), iodine 123 (^{123}I), iodine 131 (^{131}I), thallium 201 (^{201}Tl), ^{99m}Tc -sestamibi (MIBI [methyl-isobutyl-isonitrile]), fluoro-18-deoxyglucose (^{18}F FDG), gallium 67 (^{67}Ga), indium 111 (^{111}In)-octreotide, and ^{131}I -metaiodobenzylguanidine (mIBG). ^{123}I is the preferred agent for imaging substernal thyroid glands, and ^{131}I is preferred for detecting metastases after thyroid ablation.

CT evaluation of the thyroid is performed in the axial plane, usually after the intravenous (IV) administration of iodinated contrast material. The performance of CT and scintigraphic examinations must be coordinated because the administration of IV contrast material for a CT examination interferes with thyroidal uptake of radioiodine and ^{99m}Tc for 4 to 6 weeks. An advantage of CT is that the entire neck as well as the mediastinum can be surveyed for metastatic lymphadenopathy and ectopic thyroid tissue; CT also permits the detection of any unassociated concomitant conditions (Fig. 20-2). CT is excellent at characterizing the density of a thyroid lesion, thus defining the presence of calcification, cysts, or hemorrhage. The borders of a thyroid mass are usually well delineated by CT; thus, invasion of adjacent structures such as the trachea, larynx, and vascular structures of the carotid sheath can be identified.

MRI of the thyroid, like CT, can be used to evaluate the contents of the entire neck. Advantages of MRI over CT include improved soft tissue discrimination and lack of beam-hardening artifacts; however, MRI is not superior in the identification of malignant lymphadenopathy.¹⁶⁰ Differentiation between hemorrhagic lesions and lesions of increased protein content such as colloid-containing masses can be difficult, both being of either bright or dark signal

Figure 20-1. Axial T1-weighted MR postgadolinium image with fat suppression shows ovoid enhancing tissue (arrow) anterior to the larynx. The tissue, which shows the same signal intensity and enhancement as the enlarged right thyroid lobe (t), represents pyramidal lobe tissue involved by goiter (same patient as in Figure 20-27).

Figure 20-2. Axial postcontrast CT scan performed in a patient after thyroidectomy for papillary carcinoma. The heterogeneously enhancing mass (arrow) in the left neck lateral to the left common carotid artery (c) is consistent with a diagnosis of nodal metastasis.

intensity on T1-weighted and T2-weighted images. MRI also demonstrates well the relationship of thyroid lesions to adjacent structures, which assists in determining whether local invasion is present.

In most instances, fine-needle aspiration of palpable suspected thyroid masses can be accomplished freehand without imaging assistance; biopsy of small or nonpalpable lesions can be accomplished with the aid of ultrasonographic, CT, or MRI guidance.^{139, 157} Solid, hypoechoic thyroid nodules 8 mm or larger are typically selected for needle aspiration. Smaller nodules can be difficult to aspirate in a precise manner and are more often followed with serial ultrasonographic examinations. A 20- or 22-gauge needle is employed for sampling the solid portion of the mass, with imaging used to guide needle placement and avoid the common carotid artery and internal jugular vein (Fig. 20-3).

Sensitivity and specificity for fine-needle aspirations are reported to be greater than 94%, but results are highly dependent on the expertise of the cytopathologist, and nondiagnostic material may be present in as many as 20% of cases.^{7, 28, 31, 40, 43, 66, 139, 157} Fine-needle aspiration, with or without imaging guidance, is the most cost-effective method of diagnosis of primary and recurrent thyroid malignancy.

Pathologic Thyroid Conditions

Thyroid Malignancies

Malignant thyroid neoplasms constitute the most common endocrine cancer. These include the well-differentiated papillary and follicular carcinomas as well as a mixed papillary-follicular variety. Less common but more aggressive malignancies include medullary carcinoma, anaplastic carcinoma, lymphoma, metastatic disease, and other rare neoplasms, such as sarcoma. The most common of these is papillary carcinoma, which accounts for approximately 70% of all thyroid malignancies.^{67, 106, 139} Follicular carcinoma comprises about 10%; medullary carcinoma, 5%;

anaplastic carcinoma, about 5%, and the remaining malignancies together, about 1%.^{17, 67}

Imaging of thyroid neoplasms using any of a number of modalities is typically not specific for malignancy, since benign processes often simulate malignant tumors. Nodules with irregular margins or masses that invade normal local structures revealed on any imaging examination suggest a malignant process. Irregular borders are visualized in approximately 60% of thyroid malignancies, yet are also seen in approximately 45% of benign thyroid tumors.¹³⁰

Multiple small, highly echogenic foci (with or without shadowing) on sonography strongly suggest the presence of microcalcifications within malignancies.¹⁰⁹ Coarse or peripheral (eggshell) calcification, visualized on CT or with sonography, suggests a benign nodule (Fig. 20-4).¹⁰⁹ Overall, calcification is found in 13% of thyroid masses, including 17% of malignancies and 11% of benign lesions.¹³⁰

Thyroid masses with hemorrhage; cysts; diminished density, isodensity, or increased density (or signal intensity); contrast enhancement; and well-circumscribed margins examined on ultrasonography, CT, or MRI may be benign or malignant.^{90, 159} Cystic elements are found in 38% of thyroid malignancies but also in 62% of benign thyroid entities.¹³⁰

Although most thyroid carcinomas are hypoechoic at sonography, most hypoechoic nodules are benign because benign thyroid nodules are much more common than malignant thyroid nodules. Sonographically, 75% of thyroid

Figure 20-3. Ultrasound-guided, fine-needle aspiration of a thyroid mass. A 22-gauge needle (curved arrow) is being inserted into a left thyroid lobe mass (straight arrow) under real-time sonographic guidance. Cytologic examination revealed a follicular adenoma.

Figure 20-4. Axial CT scan through the lower neck shows peripheral coarse calcifications (arrowheads) in an adenoma within an enlarged, goitrous thyroid gland. This peripheral calcification may also be thin and eggshell-like.

carcinomas are hypoechoic, 23% are isoechoic, and only 2% are hyperechoic.¹³⁰ Purely cystic or completely hyperechoic nodules are very rarely malignant. Benign nodules may coexist with malignant nodules, however. For instance, 33% of thyroidectomy specimens containing papillary carcinoma also harbor benign nodules.⁴⁶

Color Doppler imaging demonstrates the vascularity of malignant and benign thyroid nodules, with malignant nodules typically showing central intranodular vascularity and benign lesions being characterized by peripheral perinodular vascularity.¹²⁴ There is considerable overlap, however, and the distribution of vessels on color Doppler imaging is not a reliable means of differentiating benign from malignant nodules.¹²⁴

More than 99% of “hot” thyroid masses on scintigraphy are benign, typically representing hyperplastic or adenomatous nodules.^{28, 50} A “cold” nodule is associated with a 15% to 25% incidence of malignancy, which increases

to as great as 50% if the patient has had earlier neck irradiation.¹¹⁶

The role of imaging includes the following:

1. Evaluation of thyroid capsule transgression.
2. Detection of neoplastic infiltration into adjacent structures, including prevertebral and local musculature, the carotid sheath, and the aerodigestive tract (Fig. 20-5).
3. Identification of malignant lymphadenopathy.

Enlarged lymph nodes, nodes demonstrating extracapsular spread, and clustered nodes suggest pathologic involvement but are not specific findings of malignant lymphadenopathy.^{131, 139} None of the imaging modalities can reliably predict malignant thyroid histology.

Papillary Carcinoma

Papillary carcinoma is characterized histologically by psammoma bodies, “ground-glass” nuclear material, and a fibrovascular papillary stroma.⁶⁷ When cyst formation is present, the carcinoma is termed a *cystadenocarcinoma*. Papillary carcinomas are often encapsulated, and they are bilateral or multifocal in 10% to 15% of cases.¹⁵² The incidence of malignant lymphadenopathy is approximately 50%,⁶⁷ and 22% of cases of malignant lymphadenopathy arise from occult thyroid tumors.⁴ Malignant nodes may be cystic, necrotic, hemorrhagic, or calcified, and they may contain colloid (Fig. 20-6).^{131, 132} In approximately 5% of patients, distant metastases occur to lungs, skeleton, or central nervous system.⁶⁷ With adequate resection, ¹³¹I therapy, and chronic suppressive therapy with thyroxine (T₄), the 20-year survival rate is reported to be 94%.⁷⁸ Tumors with both papillary and follicular components behave like purely papillary carcinomas.

Imaging of papillary carcinoma typically demonstrates a solid, hypoechoic (77%) or isoechoic (14%) thyroid mass, often with associated microcalcifications (Fig. 20-7).¹³⁰ The lesions most commonly appear to be hypofunctioning (cold) using ^{99m}Tc-pertechnetate and radioiodine (Fig. 20-8) but may demonstrate increased uptake of ²⁰¹Tl, ^{99m}Tc-MIBI, or ¹⁸FDG.

Figure 20-5. A, Axial postcontrast CT shows a heterogeneously enhancing mass (arrowheads) within the right thyroid lobe, with invasion of the cricoid ring and submucosal extension of tumor (arrow). e, esophagus. B, CT image in the same patient at a lower level shows the mass invading the trachea and esophagus (e). Papillary carcinoma was found at surgery.

Figure 20-6. Papillary carcinoma with nodal metastases. *A*, Axial postcontrast CT shows a heterogeneous, multilobular mass involving the right thyroid lobe without tracheal invasion. A peripherally calcified lymph node (*arrow*) is seen in the right tracheoesophageal groove. *B*, CT in the same patient at the level of the mandible shows two enlarged, enhancing lymph nodes (*arrows*) within the right posterior triangle and one along the left jugular chain. Normal submandibular glands (*s*).

Radioiodine uptake by functioning thyroid carcinomas and their metastases is usually less than 10% that of normal thyroid tissue. Therefore, distant and nodal metastases may not be visualized by radioiodine scanning prior to the ablation of any postoperative thyroid remnant.¹⁷ Optimal ¹³¹I uptake by neoplastic tissue is also dependent on thyroid-stimulating hormone (TSH). Adequate endogenous TSH levels of greater than 40 μ U/mL can be attained 2 weeks after the discontinuance of exogenous liothyronine (T_3) therapy or 4 to 6 weeks after the discontinuance of levothyroxine (T_4) therapy.³³ Preliminary experience indicates that the use of recombinant human TSH as a method of stimulating radioiodine uptake in patients taking exogenous thyroid hormone (TH) replacement yields a detection rate for metastases nearly equal to that seen following thyroid hormone withdrawal.⁵⁹

Thyroglobulin is an iodinated glycoprotein synthesized

by both benign and malignant thyroid tissue. Approximately 90% of patients with metastases demonstrate an elevated serum thyroglobulin level.⁷² Following surgery and ¹³¹I ablation, it should be undetectable (<5 ng/mL) if no functioning thyroid metastases remain. Serum thyroglobulin is a highly sensitive and specific indicator of

Figure 20-7. Axial postcontrast CT scan shows papillary carcinoma arising from the left thyroid lobe with calcification (*arrowhead*), central necrosis (*n*), and deviation of the intubated trachea. The mass encases the left common carotid artery (*arrow*).

Figure 20-8. An anterior view obtained during technetium 99m-pertechnetate scintigraphy shows a large solitary hypofunctioning nodule (*arrow*) in the lower pole of the left thyroid lobe. The nodule was subsequently resected and found to represent a papillary carcinoma. The right thyroid lobe is normal.

Figure 20-9. A, Several definite and a few equivocal metastatic foci (arrows) are identified in the neck and thorax 72 hours after the administration of a 3-mCi diagnostic dose of iodine 131. B, One week after administration of a 200-mCi therapeutic dose of iodine 131, whole body images more clearly define two metastatic foci in the neck (arrows) and at least five lung lesions (arrows).

residual or metastatic thyroid carcinoma in patients after ablation.

After surgery and ^{131}I ablation, patients with well-differentiated thyroid carcinoma (papillary and follicular) are assessed for recurrence annually (or less frequently) using whole body radioiodine scintigraphy and serum thyroglobulin monitoring. The sensitivity of ^{131}I scintigraphy for the detection of persistent or metastatic thyroid carcinoma is 50% to 70% with a diagnostic dose of 2 to 5 mCi.¹¹⁵ Additional lesions are often detected or more easily defined with scintigraphy following a therapeutic dose of 100 to 200 mCi (Fig. 20-9).⁸ The combination of ^{131}I scanning and serum thyroglobulin determination improves the detection of metastatic disease to 85% to 100%.⁸

Although the specificity of ^{131}I scintigraphy is high, false-positive findings related to renal, gastrointestinal (GI), other excretory pathways may be confusing. Because it is not necessary to withdraw thyroid hormone therapy prior to scanning, ^{201}Tl or $^{99\text{m}}\text{Tc}$ -MIBI imaging is more convenient for the patient. The sensitivity for either of these two agents is 60% to 90%.⁸ It is not uncommon to see a positive ^{201}Tl or $^{99\text{m}}\text{Tc}$ -MIBI scan in a thyroglobulin-positive patient with a negative ^{131}I scan (Fig. 20-10). Thyroid carcinoma metastases that are poorly visualized with ^{131}I and ^{201}Tl have been successfully imaged with ^{18}F FDG positron emission tomography (PET) while patients remained on a thyroid hormone-suppressive regimen.^{13, 126}

Ultrasonography, CT, and MRI are also effective adjunctive imaging modalities in defining the extent of metastatic disease. Compared with ^{131}I scintigraphy, diphosphonate bone scanning is insensitive in detecting the skeletal metastases of differentiated thyroid carcinoma.

Follicular Carcinoma

Follicular carcinoma is usually well margined and encapsulated, but it may be locally invasive.¹⁵⁸ Associated lymphadenopathy is seen in approximately 5% of patients,

but there is a greater propensity for hematogenous metastasis (Fig. 20-11).⁶⁷ Prognosis for follicular carcinoma is poorer than that for papillary carcinoma. Papillary elements may be present in follicular carcinomas, giving a mixed papillary-follicular variety with behavior similar to that of papillary carcinoma. Hürthle cell carcinoma is an unusual variant of follicular carcinoma that frequently demonstrates ^{201}Tl and $^{99\text{m}}\text{Tc}$ -MIBI uptake.¹ It is a nonfunctional malignancy with no radioiodine uptake.

Ultrasonography of follicular carcinomas demonstrates a hypoechoic mass in approximately 45% of cases and an isoechoic mass in the remainder (Fig. 20-12).^{34, 130} Follicular carcinoma uncommonly develops cystic regions, but compared with papillary carcinoma, it more frequently invades local vasculature, including the carotid sheath.⁶⁷ CT and MRI typically demonstrate a solid mass not dissimilar to papillary carcinoma (Fig. 20-13) and are useful for demonstrating local invasion of normal anatomy, extension into the mediastinum, and cervical lymphadenopathy. Nuclear medicine imaging characteristics are similar to those of papillary carcinomas.

Medullary Carcinoma

Medullary carcinoma of the thyroid (MCT) is derived from the parafollicular C cells, which are of neural crest origin. Approximately 80% to 90% of MCTs secrete calcitonin, which is used as a sensitive indicator of tumor presence and volume.¹⁵¹ MCTs that do not produce calcitonin have a poorer prognosis.¹⁵ Most MCTs also express carcinoembryonic antigen (CEA)¹⁵¹; early studies using radiolabeled monoclonal antibodies to CEA indicate a high sensitivity and specificity for the detection of MCT and determination of its extent (Fig. 20-14).^{5, 103} This is particularly useful for identifying MCT recurrence.

Although most MCTs express somatostatin receptors, only 40% to 60% are detected using somatostatin receptor scintigraphy (^{111}In -octreotide) (see Fig. 20-14).^{21, 58} The

Figure 20-10. Recurrence of papillary carcinoma of the thyroid. After total thyroidectomy and three treatments with iodine 131, this patient was found to have a rising serum thyroglobulin level but a negative iodine 131 whole body scan. *A*, A spot view of the anterior neck reveals no evidence of recurrence. *B*, Subsequent whole body thallium 201 scintigraphy reveals a focus of increased activity in the left neck (arrow). *C*, CT shows a mass (arrow) that was congruent with the focus seen in *B*. At exploration, recurrent carcinoma was resected.

higher the serum calcitonin level, the more likely the tumor can be detected using ^{111}In -octreotide imaging. MCT is not radioiodine-avid and cannot be treated effectively with ^{131}I . ^{201}Tl , $^{99\text{m}}\text{Tc}$ -dimercaptosuccinic acid (DMSA), and ^{131}I -mIBG have been reported to be highly sensitive and specific for MCT, especially when basal calcitonin levels are greater than 1000 pg/mL.^{6, 127} MCT may also take up ^{67}Ga . Evidence is emerging that FDG PET may represent the most effective imaging modality for detection of metastatic MCT.⁸⁹

On ultrasonographic examinations, MCTs are typically hypoechoic, although focal calcium may cause echogenic foci, both at the primary site and within metastatic lymph nodes.^{8, 34, 130} CT and MRI demonstrate a solid mass, are helpful for displaying surgical anatomy, and best reveal adjacent lymphadenopathy; malignant lymph nodes are seen in approximately 50% of cases.¹⁵⁸ CT and MRI are often inadequate for identifying MCT recurrences.²¹ Selective venous sampling for calcitonin levels using transfemoral catheter techniques is a sensitive and specific method

of localizing MCT, but it is invasive, time consuming, and expensive.⁸⁸

MCT is most often sporadic, but a familial link is seen in approximately 15% of adult patients.¹⁵⁸ MCT is a component of multiple endocrine neoplasia type 2A (MEN-2A) and type 2B (MEN-2B) syndromes. MEN-2A is called Sipple's syndrome and MEN-2B (or MEN-3) is termed the *mucosal neuroma syndrome*. In MEN-2A, virtually all patients have MCT, one third have parathyroid hyperplasia, and roughly one third harbor pheochromocytomas. Patients with the MEN-2B syndrome, in addition to having MCT, demonstrate mucocutaneous and alimentary tract gangli-neuromas, café-au-lait spots, and marfanoid facies; in addition, pheochromocytomas develop. A missense mutation of the *ret* oncogene has been identified on chromosome 10 in families with either the MEN-2A or the MEN-2B syndrome.⁸⁸

Anaplastic Carcinoma

Anaplastic carcinoma, typically seen in older patients, is a very aggressive head and neck malignancy that carries

Figure 20-11. A, Axial postcontrast CT scan of the head shows a large destructive mass within the posterior calvaria. The lesion has a thick enhancing peripheral rim of soft tissue with central low attenuation and calcification (arrowheads). The brain parenchyma does not appear to be invaded. B, Axial CT scan through the upper thorax using lung window technique shows multiple parenchymal metastases (arrowheads) in both lungs. C, Axial CT scan through the lower neck shows papillary carcinoma of the right thyroid lobe with multiple calcifications. This lesion had metastasized to the calvaria and lungs.

a poor prognosis.¹⁵⁸ Patients typically survive only a few months after the pathologic diagnosis is confirmed. Metastases are often widespread. This type of thyroid malignancy can be present within goiter or may be associated with other thyroid malignancies.^{67, 122}

Conventional nuclear medicine techniques using ^{99m}Tc-pertechnetate or radioiodine demonstrate only a nonspecific hypofunctioning mass. ²⁰¹Tl, ^{99m}Tc-MIBI, and ¹⁸F-FDG reveal increased activity within the primary mass as well as within metastases.¹²² Although these tumors are ⁶⁷Ga-avid, this radionuclide cannot be used to differentiate anaplastic carcinoma from other malignancies, thyroiditis, or thyroid granulomatous infections.

On ultrasonography, anaplastic thyroid carcinoma typically appears as a large hypoechoic mass.^{34, 116} CT demonstrates calcification in approximately 60% of cases and necrosis in 75%.¹⁴² Metastatic lymphadenopathy develops in approximately 75% of patients, and in 50% of these the

lymph nodes are necrotic.¹⁴² Local invasion of vasculature or the aerodigestive tract is seen in approximately 40% of patients (Figs. 20-15 and 20-16),¹⁵ and in 25% the malignancy extends into the mediastinum (Fig. 20-17).¹⁴² CT, MRI, and ultrasonography can be used to evaluate the extent of local disease, although ultrasonography does not allow visualization of caudal advancement into the mediastinum.¹⁴²

Lymphoma

Primary lymphoma of the thyroid gland is usually a B-cell neoplasm and is most commonly seen in older women with current or prior Hashimoto's thyroiditis.^{41, 67} Virtually all patients with primary lymphoma of the thyroid have coexistent autoimmune thyroiditis.⁴¹

Lymphomas typically appear as solitary (80%) or multifocal hypoechoic nodules (20%) on ultrasonographic

Figure 20-12. Follicular carcinoma of the thyroid. A predominantly hypoechoic heterogeneous mass (*arrow*) with central vascularity (indicated by Doppler enhancement) is seen within the right lobe of the thyroid. *Curved arrow* indicates common carotid artery.

Figure 20-13. A, Axial CT image shows a lobular mass arising from the left lobe of the thyroid; it has a slight mass effect on the trachea. B, Axial T2-weighted MR image demonstrates a predominantly hyperintense mass splaying the bilateral common carotid arteries (c) and internal jugular veins (j). There is no evidence of tracheal invasion. C, Axial T1-weighted MR image demonstrates that the mass is of intermediate signal intensity. D, Axial T1-weighted MR image after contrast administration shows diffuse enhancement throughout the mass. Follicular carcinoma without tracheal invasion was seen at surgery.

Figure 20-14. A, Following total thyroidectomy, a patient with medullary carcinoma of the thyroid and persistent elevation of serum calcitonin and carcinoembryonic antigen (CEA) was found to have a negative indium 111-octreotide scan. B, Whole body and SPECT imaging with iodine 131-labeled anti-CEA monoclonal antibody (performed at Garden State Cancer Center, Newark, N.J.) revealed two metastatic foci in the mediastinum (*arrows*). CT scan (not shown) did not demonstrate liver metastases. (From Martin WH, Delbeke D, Habibian MR: *Oncologic imaging*. In Habibian MR, Delbeke D, Martin WH, Sandler MP [eds]: *Nuclear Medicine Imaging: A Teaching File*. Philadelphia, Lippincott Williams & Wilkins, 1999, p 700).

studies,^{34, 130, 141} and they are photopenic on ^{99m}Tc -pertechnetate or radioiodine scintigraphy. Although lymphomas accumulate both ^{67}Ga and ^{18}F FDG, so may the adjacent areas involved by autoimmune thyroiditis. Gallium 67 and ^{18}F FDG, however, may demonstrate distant metastases.⁵² Most lymphomas accumulate ^{201}Tl and ^{99m}Tc -MIBI, both of which may be used to assess response to therapy.¹²⁰ These tumors are isodense or hypodense on CT, without or with IV contrast material, and typically cause homogeneous enlargement of a lobe or of the entire thyroid (Fig. 20-18).¹⁴¹ Necrosis or calcification is seen in a minority of

cases.¹⁴¹ Local invasion (19% to 51%) or metastasis to regional lymph nodes (14% to 44%)¹⁴¹ can be demonstrated by ultrasonography, CT, and MRI, each modality having its own advantages and limitations.¹⁴³ On MRI, lymphoma often shows increased signal intensity on T2-weighted images¹²³ and enhances less compared with other thyroid tumors.⁹⁰

Metastases

Approximately 3% of individuals with a primary malignancy outside the thyroid gland have metastatic disease to

Figure 20-15. Anaplastic carcinoma. A, Axial postcontrast CT image shows an enhancing mass arising from the left thyroid lobe with invasion of the esophagus (*arrowheads*) and left carotid sheath. c, left common carotid artery; *arrow* indicates left internal jugular vein. B, CT scan of the same patient at the level of the true vocal cords shows the superior extent of the invasive tumor as it insinuates itself between the thyroid cartilage and the strap musculature (*arrowheads*). Invasion of the left thyroid ala has occurred (*white arrow*). An enhancing pathologic lymph node (*black arrow*) can be seen on the left, with spiculated margins indicative of extracapsular spread of tumor.

Figure 20-16. Anaplastic thyroid carcinoma. *A*, Axial postcontrast CT scan shows a large right thyroid lobe mass with tracheal invasion (arrows). The lesion marginates but does not surround the right common carotid artery (arrowheads). An endotracheal tube is in place. *B*, Axial CT scan through the thorax in the same patient shows multiple pulmonary metastases (arrows).

the thyroid at autopsy.¹¹⁹ The two most common malignancies to metastasize to the thyroid are bronchogenic carcinoma and renal cell carcinoma. The appearance of metastatic lesions is nonspecific and may be multifocal. These lesions usually occur in the context of widespread metastases.

Other Malignant Neoplasms and Teratomas

Leukemic infiltration of the thyroid may mimic the imaging appearance of lymphoma. Squamous cell carcinoma, mucoepidermoid carcinoma, and columnar cell carcinoma of the thyroid gland have been reported sporadically. Other rare tumors of the thyroid, such as teratomas and sarcomas, typically present as solid masses. Teratomas are typically midline masses, usually contain fatty as well

as soft tissue elements and fluid, frequently calcify, and may have well-developed teeth and osseous elements.^{158, 159} As with other neoplasms, ultrasonography, CT, or MRI is helpful for identifying regional lymphadenopathy and local invasion in malignant varieties.

Benign Thyroid Neoplasms

More than 95% of thyroid nodules are benign.⁸⁷ Most of these are hyperplastic (colloid) nodules (Fig. 20-19), and the remainder are adenomas. Solitary hyperplastic nodules are common incidental findings at sonography. It is estimated that 40% or more of the general population have thyroid nodules that are detectable with modern high-resolution sonography.¹¹²

The number of nodules increases with age. Thyroid nodules can be solid, cystic, or mixed, appearing isoechoic

Figure 20-17. Anaplastic carcinoma. Axial postcontrast CT image demonstrates a lobulated, heterogeneously enhancing left thyroid lobe mass surrounding the left common carotid artery (arrowhead) and displacing the left subclavian artery (arrow) posteriorly. The mass extends into the upper mediastinum.

Figure 20-18. Thyroid lymphoma. Axial CT scan at the thoracic inlet shows marked thyroid enlargement involving both lobes and the isthmus. The gland is homogeneous in density, and no calcifications are present. The tracheal airway is compromised and an endotracheal tube (arrowhead) is in place.

Figure 20-19. Axial postcontrast CT image shows a well-circumscribed, homogeneous, low-density mass within the left thyroid lobe. Despite its low density, the lesion is not cystic. The diagnosis was a hyperplastic thyroid nodule.

with a hypoechoic margin (or halo), hypoechoic, or hyperechoic. The presence of a hypoechoic halo makes the lesion 4 to 12 times more likely to be benign.¹³⁰ Cystic, degenerating nodules tend to have thicker walls than simple cysts and often contain solid components.

Thyroid Adenomas

Thyroid adenomas are seen more commonly in women. They are usually less than 3 cm in diameter, have well-delineated margins, and may become cystic, may involute, or may develop internal hemorrhage, necrosis, calcification, or fibrosis.¹⁵⁸ Most thyroid adenomas are hyperechoic or isoechoic at ultrasonography (see Fig. 20-3), whereas most carcinomas are hypoechoic, sometimes with poorly defined borders. Echogenicity alone cannot differentiate between benign and malignant nodules, however (see preceding discussion). Thyroid adenomas are typically of increased signal intensity on T2-weighted MR images but are often heterogeneous (Fig. 20-20).³⁰ They enhance on both CT and MR images and on CT scans appear solid or cystic when the adenoma has degenerated (see Fig. 20-4).

Thyroid adenomas may be *functioning* or *nonfunctioning*. Functioning thyroid adenomas may be autonomous or hypertrophic, and both types may result in hyperthyroidism with suppressed TSH levels but usually not until the adenoma is larger than 2.5 cm in diameter.²⁸ Plummer's disease defines a solitary or several autonomous hyperfunctioning (hot) nodules within an enlarged thyroid gland that are unresponsive to administration of exogenous thyroid hormone.

Both hypertrophic and autonomous functioning thyroid adenomas avidly take up ^{99m}Tc-pertechnetate and radioiodine (Fig. 20-21). A hypertrophic functioning adenoma appears cold after the administration of exogenous thyroid hormone, whereas an autonomous functioning nodule remains hot.¹¹⁶ Other thyroid conditions that demonstrate avid uptake of ^{99m}Tc-pertechnetate include rare malignancies, ectopic thyroid tissue, some normal thyroid variants, and thyroiditis.¹⁰⁶ Radioiodine is more specific than ^{99m}Tc-pertechnetate in identifying a functioning thyroid adenoma.

When ^{99m}Tc-pertechnetate or ¹²³I is used, nonfunctioning

thyroid adenomas appear photopenic compared with adjacent uninvolved thyroid tissue, which is identical to findings with papillary carcinoma (see Fig. 20-8). Numerous other benign entities may appear similarly cold, including degenerated follicular adenomas, adenomatous hemorrhage, cysts, nodular goiters, amyloid deposition, and inflammatory disorders.¹¹⁶ Although most thyroid malignancies are cold, 75% to 85% of solitary cold nodules are benign.¹³³ Fine-needle aspiration biopsy may be used to characterize solitary cold thyroid nodules with high sensitivity and specificity.⁴⁰

Thyroid Cysts

Thyroid cysts are also nonfunctioning cold thyroid masses. True thyroid cysts are rare, representing fewer than 1% of all thyroid masses. Most cystic masses are degenerating adenomatous nodules.¹⁵⁸ These are anechoic with thin walls and through-transmission on ultrasonography (Fig. 20-22), of low density on CT (Fig. 20-23) and of increased signal intensity on T2-weighted MR images, and they may show decreased or increased signal intensity on T1-weighted MR images. The increased signal intensity on T1-weighted images is related to the presence of hemorrhage, colloid, or increased protein content. Colloid cysts typically demonstrate such increased signal intensity on T1-weighted MR images.¹¹⁶ CT density also increases with infection or spontaneous or traumatic internal hemorrhage. Any cystic thyroid mass with a solid component must be approached with suspicion for malignancy (especially papillary carcinoma), although a completely cystic nodule with uniformly thin walls is almost always benign.

Goiter and Multinodular Goiter

The enlarged thyroid, termed a *goiter*, may be hypofunctioning, hyperfunctioning, or normally functioning. The enlarged thyroid may present as a neck mass with or without tracheal or esophageal compression. Thyroid enlargement is best determined by measuring the diameter of the isthmus or the anterior-posterior diameter of the thyroid lobes. The normal isthmus is less than 6 mm in thickness, and each thyroid lobe measures less than 20 to 25 mm in the anterior-posterior dimension. The association of thyroid carcinoma with goiter is less than 3%.⁸³

With scintigraphy, multinodular goiter most often demonstrates heterogeneous distribution of the radiopharmaceutical, with foci of increased and decreased activity (Fig. 20-24). Ultrasonography well demonstrates individual nodules within a goiter (Fig. 20-25). These nodules may be palpable or nonpalpable, regardless of whether the patient has clinically evident thyroid disease. Doppler imaging often reveals hypervascularity throughout the goiter. Pathologic characterization of each nodule within a goiter by imaging is unreliable unless typical malignant characteristics are demonstrated (see preceding discussion) or unless the nodule is hot and thus benign on nuclear medicine scintigraphy. The rare occurrence of papillary carcinoma representing one or more of the thyroid nodules is a consideration, although it is unlikely. Multiple cold nodules within a goiter may obviate the need for biopsy; however, an enlarging or dominant mass should prompt histologic evaluation.^{116, 125}

Figure 20-20. Follicular adenoma. *A*, Sagittal T2-weighted MR image demonstrates a mixed-signal-intensity ovoid mass (*arrow*) within the lower pole of the left thyroid gland. The lesion is peripherally hyperintense with a central nodule of intermediate signal. The normal thyroid parenchyma (*asterisk*) is homogeneously hypointense. *B*, Sagittal T1-weighted MR image shows the mass (*arrow*) to be of intermediate signal intensity but distinguishable from normal parenchyma. *C*, Coronal T1-weighted postgadolinium MR image shows enhancement of the peripheral component of the mass (*arrow*) with no appreciable enhancement of the central nodule. Note the relationship of the mass to the trachea (*asterisk*) and left common carotid artery (*arrowhead*). *D*, Axial postcontrast CT scan shows the well-circumscribed mass (*arrow*) in the posterior left thyroid lobe, with mixed attenuation. The imaging features of the nodule are nonspecific.

Figure 20-21. With technetium 99m-pertechnetate scintigraphy, an anterior view identifies a solitary hyperfunctioning nodule in the upper pole of the right thyroid lobe. Extranodular thyroid activity is not suppressed, consistent with a diagnosis of euthyroidism.

Ultrasonographic and CT imaging typically demonstrate the goitrous thyroid as heterogeneous and display nodular enlargement of one or both lobes with cysts and often calcification (Fig. 20-26). Hemorrhage may be seen in 60% of cases.⁹⁵ On an MR image, multinodular goiter is typically heterogeneous; signal intensity is isointense to normal thyroid or increased on T1-weighted images and mixed on T2-weighted images.^{30, 95} Contrast enhancement

Figure 20-22. Transverse sonogram of the thyroid performed with an extended field of view (Siescape [Siemens]) shows the entire thyroid and adjacent structures. The right and left lobes are separated by the trachea (t). The isthmus lies superficial to the trachea. Simple cysts (arrows) are seen in the right and left lobes, which are otherwise normal. Curved arrows indicate common carotid arteries; asterisks show internal jugular veins.

Figure 20-23. Axial postcontrast CT image demonstrates a well-circumscribed, low-density colloid cyst (C) within the right lobe of the thyroid. The nongoitrous thyroid parenchyma at the periphery of the lesion enhances normally (arrowheads).

is typically diffuse and mottled on CT and MRI scans (Fig. 20-27). In some instances, all imaging modalities demonstrate a uniform parenchymal appearance in an enlarged thyroid gland.

Ultrasonography is not an imaging option for evaluating the possibility of a substernal goiter because the sternum prevents mediastinal interrogation. CT and MRI, however, demonstrate a substernal goiter well, and both may reveal cervical thyroid tissue contiguous with the mediastinal mass (Fig. 20-28). If a radionuclide scan is contemplated, iodinated contrast media should be withheld during CT scanning because these agents may precipitate thyroid storm in some thyrotoxic patients. Because of the presence of interfering mediastinal blood pool activity with ^{99m}Tc-pertechnetate, ¹²³I should be used to assess mediastinal masses.

Figure 20-24. An asymmetrical thyroid gland with multiple foci of increased (long-stemmed arrow) and decreased (arrows) uptake of technetium 99m-pertechnetate is typical of multinodular goiter, but it may also be seen in Hashimoto's thyroiditis.

Hyperthyroidism

Hyperthyroidism may be caused by Graves' disease (diffuse toxic goiter), toxic nodular goiter (Plummer's disease), autonomous toxic adenomas, and, rarely, ectopic thyroid tissue, thyroid inflammation, or bulky differentiated carcinoma. At scintigraphy, uptake of the radiopharmaceutical within the gland or each functioning nodule is increased, and background and salivary gland activity are diminished. In the case of a toxic nodule, activity within the remainder of the gland is suppressed (Fig. 20-29).

Women are 10 times more likely than men to have hyperthyroidism. The diagnosis is made by the detection of elevated circulating levels of thyroid hormones, accompanied by suppressed TSH levels in all cases other than those caused by a TSH-producing pituitary adenoma. Elevated or high-normal radioiodine uptake confirms that the thyroid is hyperfunctional. Suppressed thyroid uptake generally indicates that the hyperthyroidism is caused by exogenous administration of thyroid hormone or that it is the result of thyroid parenchymal destruction due to subacute thyroiditis or postpartum thyroiditis; a rare alternative is struma ovarii (a thyroxine-producing ovarian teratoma).¹⁵⁵

Patients with elevated serum thyroid hormone levels and increased thyroidal radioactive iodine uptake at 24 hours typically have Graves' disease or toxic nodular goiter. Patients with elevated thyroid function test findings and normal radioactive iodine uptake typically have Plummer's disease or a Graves' disease variant with rapid iodine turnover.

Percutaneous ethanol ablation of autonomous thyroid nodules has been successful in treating hyperthyroidism.^{19, 69, 101}

Figure 20-25. Multinodular goiter. Sagittal sonographic image of the right lobe of the thyroid reveals a heterogeneous, enlarged thyroid with predominantly hyperechoic (large arrow) but also hypoechoic (small arrow) nodules.

Figure 20-26. Multinodular goiter. CT scan at the level of the cricoid cartilage shows bilaterally enlarged, heterogeneous thyroid lobes. Several foci of calcification (arrowheads) are seen within the larger right lobe. The common carotid arteries (c) and internal jugular veins (j) are displaced posterolaterally.

Graves' Disease

Graves' disease is the most common cause of hyperthyroidism. It occurs most often in young women, is related to abnormal production of a thyroid stimulating immunoglobulin, and may be familial.

On CT or MR images, patients with Graves' disease demonstrate a diffusely enlarged, contrast-enhancing thyroid gland.¹⁵⁸ A hypertrophied pyramidal lobe is a common accompaniment.¹⁵⁸ Sonographically, the gland appears diffusely hypoechoic and markedly hypervascular by Doppler flow imaging ("thyroid inferno").¹⁰⁷ Nuclear medicine scintigraphy reveals markedly elevated iodine uptake by a diffusely enlarged thyroid gland (Fig. 20-30). Occasionally, a patient with Graves' disease has an enlarged thyroid gland with one or more nodules. Although a solitary cold solid nodule in a patient with Graves' disease may represent an area of nonfunctioning, TSH-dependent, hyperplastic tissue (Marine-Lenhart disease),¹¹⁶ the possibility of coexistent malignancy must be entertained. Fine-needle aspiration biopsy is usually recommended and is safe despite the hypervascularity of the gland. Malignant thyroid tumors are seen only rarely in patients with Graves' disease (~0.5% of reported cases).^{15, 25}

Orbital findings in patients with Graves' disease include exophthalmos, increased extraocular muscle thickness, and excessive retrobulbar fat.

Hypothyroidism

Hypothyroidism is diagnosed more often in women than in men, and the condition is found in as many as 3% to 5% of people older than age 65.¹⁵⁹ In the Western world, autoimmune Hashimoto's thyroiditis is the most common cause of hypothyroidism; worldwide, however, iodine deficiency is the leading cause of endemic goiter. Other

Figure 20-27. A, Axial T2-weighted MR image demonstrates a large goiter (g) involving the right thyroid lobe. It displaces the right common carotid artery (arrow) laterally and displaces and compresses the trachea (t). The goiter is relatively homogeneous and shows slightly increased signal. B, Axial T1-weighted image shows that the goiter (g) is of intermediate signal intensity. C, After gadolinium administration, the goiter (g) shows diffuse enhancement on this T1-weighted sequence.

causes include previous thyroidectomy, previous radiation (^{131}I or external beam), congenital organification defects, subacute or chronic thyroiditis, dietary or environmental goitrogens, antithyroid medications such as propylthiouracil (PTU) and methimazole, hypothalamic or pituitary disease, and exogenous iodine (medications, foods, contrast agents). Radioiodine uptake is low or low-normal in patients with hypothyroidism except when caused by iodine deficiency.

Congenital hypothyroidism may be secondary to thyroid aplasia, hypoplasia or hemiaphasia, thyroid ectopia, abnormal thyroxine production, pituitary or hypothalamic disorders, or autoimmune disease. In the infant with congenital hypothyroidism, a $^{99\text{m}}\text{Tc}$ -pertechnetate scan is often used to detect the amount of normally located thyroid gland and any ectopic functioning tissue. Scintigraphy and other imaging modalities are usually not necessary in the remainder of patients with hypothyroidism.

Figure 20-28. Substernal goiter. CT scan through the upper thorax shows an enlarged thyroid gland posterior to the sternum (S). Both lobes are symmetrically enlarged, with slight heterogeneity of the parenchyma. The trachea (asterisk) is slightly compressed in the midline, and the great vessels are displaced laterally. Neither tracheal nor esophageal (arrows) invasion has occurred.

Thyroid Inflammatory Disorders

Bacterial Thyroiditis

Bacterial thyroiditis may be spontaneous, may arise from hematologic seeding, may occur in an immune-compromised host, may result from a cervical puncture wound, may develop because of an infected third or fourth branchial cleft cyst (usually left-sided),^{2, 44} or may arise from an aerodigestive tract or thyroglossal duct fistula.⁵³ It typically follows a fulminant course. MRI or CT scans of acute bacterial thyroiditis are sometimes used to evaluate airway compromise, associated lymphadenopathy, carotid sheath inflammation (including jugular vein thrombosis), and associated congenital cysts) and to identify fistulous tracts and abscesses.¹⁶

De Quervain's Thyroiditis

De Quervain's thyroiditis (or subacute granulomatous thyroiditis) is a subacute condition that usually presents with a diffusely tender thyroid in middle-aged women following a viral respiratory tract infection. Coxsackievirus, adenovirus, echovirus (enteric cytopathogenic human orphan virus), influenza virus, and mumps virus have been implicated as causative agents.^{67, 149} Approximately 50% of patients present with mild, transient, destruction-induced hyperthyroidism followed by mild hypothyroidism, eventually returning to euthyroidism over a period of 6 to 9 months.^{106, 119}

Sonographically, the thyroid gland appears hypo-

Figure 20-29. With technetium ^{99m}Tc -pertechnetate, a solitary large focus of increased activity is identified in the left neck. The lack of contralateral thyroid activity and the virtual absence of background activity are consistent with a diagnosis of solitary toxic adenoma. The suprasternal notch is identified with a cobalt marker (arrow).

Figure 20-30. Diffusely increased radionuclide uptake in an enlarged gland is typical of Graves' disease. Background activity is absent and the isthmus is thickened.

echoic.³⁴ Uptake of radioiodine (or ^{99m}Tc -pertechnetate) is heterogeneous and initially low (0% to 5%); it later becomes elevated before returning to normal. On ultrasonography, MRI, CT, or nuclear scintigraphy, the end-stage thyroid gland may be atrophic, although this is rare. More than 90% of patients with subacute thyroiditis have a normal thyroid gland with normal function and normal appearance on any imaging test at long-term follow-up.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis is a chronic lymphocytic infiltration of the thyroid. It is the most common of the thyroiditides, it primarily occurs in women between ages 40 and 60 years, and it is the most common thyroiditis in children.¹⁵⁸ The disease is caused by an autoimmune response to thyroglobulin, colloid, or other thyroid antigens. Other autoimmune diseases may be associated, such as adrenal insufficiency, pernicious anemia, and systemic lupus erythematosus. More than 50% of patients with Hashimoto's thyroiditis are hypothyroid.¹⁵⁸ There is also a predisposition for development of non-Hodgkin's lymphoma.¹⁴¹

The radionuclide scan may be normal, may reveal a homogeneously enlarged gland, or may demonstrate diffuse heterogeneous activity; in some patients, a solitary region of photopenia may be seen. Radioiodine uptake may be normal, low, or high.²⁵ The affected gland frequently accumulates ^{18}F FDG or ^{67}Ga .¹⁵⁴

At ultrasonography, the thyroid gland is enlarged and diffusely hypoechoic or multinodular (Fig. 20-31).¹⁵⁶ Calcification may be seen on CT or ultrasonography (Fig. 20-32). On T2-weighted MR images, Hashimoto's thyroiditis typically demonstrates increased signal intensity, sometimes with linear, low-signal-intensity strands, possibly representing fibrosis.^{30, 104}

Riedel's Thyroiditis

Riedel's thyroiditis, also termed struma thyroiditis, is a rare chronic inflammatory condition of the thyroid gland. The gland enlarges and may demonstrate regional mass effect with hoarseness and dysphagia caused by the extensive associated neck fibrosis. The condition is more com-

Figure 20-31. A, Sagittal ultrasound image of the right thyroid lobe shows an enlarged lobe with homogeneous, slightly hypoechoic echotexture. No focal nodules, cysts, or calcifications are noted in this patient with Hashimoto's thyroiditis. B, Transverse ultrasound image shows homogeneous, hypoechoic parenchyma with enlargement of the thyroid isthmus (i) as well as both lobes. The centrally located trachea (t) demonstrates artifact posterior to it generated by internal air.

mon in women. It may affect one or both thyroid lobes and typically causes hypothyroidism.

At imaging, the thyroid appears enlarged and homogeneously hypoechoic on ultrasonography and hypodense on CT.^{34, 104} Riedel's thyroiditis may mimic malignancy with local infiltration, and it often calls for surgery for definitive diagnosis and relief of compressive symptoms.

Diminished signal intensity on T1-weighted and T2-weighted MR images is thought to be caused by chronic fibrosis.¹⁰⁴ Riedel's thyroiditis may be associated with other fibrotic conditions such as retroperitoneal fibrosis, mediastinal fibrosis, sclerosing cholangitis, and orbital pseudotumor.⁷⁰

Figure 20-32. Unenhanced CT scan shows a diffusely enlarged, homogeneous thyroid gland in a patient with Hashimoto's thyroiditis. No focal masses or calcifications are noted.

Miscellaneous Thyroid Conditions

Other inflammatory but rare thyroid conditions include tuberculosis, sarcoidosis, fungal diseases, and opportunistic organisms, especially in patients with acquired immunodeficiency syndrome (AIDS). Amyloidosis and hemochromatosis may replace thyroid parenchyma and may cause decreased signal intensity on T2-weighted MR images.¹⁵⁸ Radiation received from external beam or radioactive iodine therapy may lead to fibrosis and atrophy of the thyroid gland.

Developmental Thyroid Anomalies

Lingual Thyroid

Lingual thyroid results from arrest of migration of the thyroid anlage at the foramen cecum in the base of the tongue to its normal location in the anterior neck. The condition occurs in one in 3000 patients with thyroid disease, and it is the most common form of functioning ectopic thyroid tissue (90% of cases).¹¹⁹ Arrest of migration may be complete or incomplete, typically occurring in the midline of the tongue base between the circumvallate papillae and the epiglottis. Rare cases may involve the entire tongue. Thyroid tissue in its normal location in the neck is absent in 70% to 80% of cases,^{38, 119} and most of these patients are hypothyroid.

Ectopic thyroid tissue is more common in women than men (7:1) and may present as an enlarging mass at puberty or during pregnancy secondary to hormonal changes.¹⁵⁸ Malignancy in lingual thyroid tissue occurs in 2.8% of cases.⁸⁵

Radionuclide ^{99m}Tc-pertechnetate, ¹²³I, or ¹³¹I scintigraphy demonstrates avid tracer uptake within the midline of

Figure 20-33. Lingual thyroid. Frontal projection of a technetium 99m -pertechnetate thyroid scan shows prominent uptake of radiotracer in the base of the tongue (*arrowheads*). Tracer uptake is absent where it would be expected in the thyroid tissue in the lower neck. Normal uptake is noted in the parotid (*arrows*) and submandibular (*open arrows*) glands.

the tongue base if a lingual thyroid is present (Fig. 20-33). If surgery is contemplated, radionuclide evaluation with ^{123}I or ^{99m}Tc -pertechnetate is recommended to detect additional functioning thyroid tissue in the neck. Unenhanced CT

shows a hyperdense mass in the base of the tongue. With iodinated contrast material, the lingual thyroid densely and homogeneously enhances (Fig. 20-34).

MRI shows lingual thyroid tissue to be isointense to normal thyroid tissue on T1-weighted images and hyperintense on T2-weighted images.³⁸ The mass enhances strongly after administration of gadolinium-based contrast material. Additional thyroid tissue lower in the neck may be identified with either CT or MRI.

Thyroglossal Duct Cyst

The thyroglossal duct cyst (TDC) is the most common congenital cystic neck mass, accounting for 70% of nonodontogenic congenital neck abnormalities. The thyroglossal duct is the embryologic tract along which the thyroid anlage courses as it descends from the foramen cecum in the tongue base to its normal location in the low anterior neck. TDCs may occur anywhere along the course of the duct but typically occur about the hyoid bone. The majority of cysts (65%) are located within the thyrohyoid membrane and are infrahyoid in location.³ Fifteen percent of TDCs are at the level of the hyoid, and 20% are suprahyoid.³ Suprahyoid TDCs are more likely to be at the midline, imbedded between the anterior bellies of the digastric muscles. Infrahyoid lesions are paramedian and tend to be located within the strap musculature. Two percent are completely intralingual.

Most TDCs present in young adulthood, with 50% occurring before age 10 years and 70% before age 30. Rarely, they may present in older adults. There is no known sex

Figure 20-34. A, Enhanced CT image at the level of the oropharynx shows a well-circumscribed, homogeneously enhancing mass (*arrows*) in the tongue base, consistent with a diagnosis of ectopic lingual thyroid tissue. B, CT scan in the same patient at the expected level of the thyroid gland demonstrates no paratracheal thyroid tissue (*arrowheads*).

Figure 20-35. Thyroglossal duct cyst. *A*, Axial postcontrast CT scan at the level of the hyoid bone shows a multilobulated low-density mass traversing the hyoid bone. A component of the lesion is deep to the hyoid within the pre-epiglottic fat (arrow), and the remainder is seen anterior to the hyoid (white arrowheads). The bone defect can be seen within the central aspect of the hyoid bone (black arrowhead). Note also the submandibular glands (s). *B*, Axial CT scan in the same patient 5 mm caudal to *A* shows two low-attenuation components of the mass (asterisks) and their relationship to the hyoid bone. Submandibular glands are normal.

predilection. Coexisting carcinoma, usually of the papillary type, occurs in 1% of patients with TDC.^{3, 45, 47} Follicular carcinoma, adenocarcinoma, and squamous cell carcinoma have been reported. Ectopic thyroid tissue is present within the wall of TDC in fewer than 5% of cases.^{3, 97}

CT demonstrates a unilocular or multilocular low-density mass, usually 2 to 4 cm in diameter, present anywhere from the tongue base to the superior margin of the thyroid gland. When located within the hyoid bone, a defect in the bone itself may be apparent on CT (Fig. 20-35). TDC contents may be isodense to hyperdense because of increased protein content or hemorrhage. The capsule of the lesion may uncommonly enhance unless the patient has a history of trauma or current or previous infection. Prior or active superinfection is seen in approximately 60% of patients. Enhancement of the surrounding musculature and obscuration of fascial planes indicate TDC superinfection and overlying cellulitis (Fig. 20-36). Nodules of enhancing tissue within the cyst raise the possibility of concurrent malignancy but may represent only ectopic thyroid tissue.

MRI signal characteristics vary, depending on the protein content of the fluid within the cyst. TDCs most commonly show low to intermediate signal intensity on T1-weighted images, increased signal intensity when proteinaceous, and high signal on T2-weighted images (Fig. 20-37).

With both CT and MRI, enhancing ectopic thyroid tissue may be seen along the course of the thyroglossal duct. Scintigraphy is more sensitive in the detection of these ectopic thyroid rests. Ultrasonography of a TDC displays an anechoic, cystic mass with through-transmission. Inter-

nal echoes within the cyst may be caused by increased protein content or hemorrhage. Both ultrasonographic and nuclear medicine imaging can confirm the presence of a normal thyroid gland before TDC resection.⁶⁵

Parathyroid Glands

Typically, four parathyroid glands are present (two superiorly and two inferiorly) along the posterior margins of

Figure 20-36. Infected thyroglossal duct cyst. Axial postcontrast CT scan at the level of the upper thyroid cartilage demonstrates an enhancing, slightly heterogeneous soft tissue mass (arrow) within the anterior cervical space. Stranding within the fat surrounding the lesion suggests infection.

Figure 20-37. Thyroglossal duct cyst. *A*, Axial T1-weighted MR image just inferior to the hyoid bone shows a rounded, low-signal-intensity mass (*black arrow*) in the anterior pre-epiglottic fat at the superior margin of the thyroid cartilage. The normal epiglottis (*white arrow*) is demonstrated. *B*, Axial T2-weighted image slightly inferior to *A* shows the lesion (*arrow*) extending anterior to the thyroid cartilage (*arrowheads*) between the strap muscles. The lesion shows increased signal intensity on the T2-weighted sequence.

both lobes of the thyroid; however, the location of the inferior parathyroid glands may vary. In approximately 20% of patients, they are located anywhere from the carotid bifurcations to the upper mediastinum as well as within the thyroid or behind the trachea or esophagus.^{28, 35, 92, 106} Ten percent to 25% of patients have more than four parathyroid glands, with the supernumerary glands most often found in the upper mediastinum.^{67, 68}

Parathyroid pathology may be detected by radionuclide scintigraphy, ultrasonography, CT, MRI, angiography, and venous sampling. The success of all of these techniques, except venous sampling, depends, to a varying degree, on the size of the abnormal gland.

The radiopharmaceutical of choice for imaging parathyroid enlargement is ^{99m}Tc-MIBI, employing a double-phase protocol.^{36, 62, 77, 84} ^{99m}Tc-MIBI accumulates in both parathyroid and thyroid glands but is retained longer in pathologic parathyroid tissue. Imaging 2 to 3 hours after ^{99m}Tc-MIBI injection allows physiologic washout of thyroid radioactivity but persistent accumulation within the abnormal parathyroid tissue (Fig. 20-38).¹⁴⁰ Increased mitochondrial content in parathyroid adenomas is believed to be responsible for the observed MIBI concentration.⁹⁹ Because of the high sensitivity of MIBI scintigraphy (80% to 90%) in detecting parathyroid adenomas,^{99, 100, 140} ^{99m}Tc/²⁰¹Tl subtraction imaging is used only rarely in current clinical practice.⁷⁶ Oblique planar views and single photon emission computed tomography (SPECT) have been reported to improve sensitivity and localization of abnormal parathyroid glands.^{86, 93, 105, 118} Subtraction of thyroid activity with ¹²³I may be used with MIBI and can be useful when concomitant thyroid disease is suspected.⁹

Ultrasonographic evaluation of the parathyroid gland employs a 7- to 10-MHz transducer and adequately delineates parathyroid gland enlargement when the glands are located in characteristic parathyroid locations. Normal parathyroid glands are not detected. When parathyroid gland enlargement is not found in the region of the thyroid, the entire anterior neck from mandible to suprasternal notch

is examined sonographically, including the retrotracheal region via a lateral approach; however, ectopic parathyroid gland location in the neck may escape ultrasonographic detection. Ultrasonography cannot be used to identify mediastinal parathyroid adenomas. Parathyroid masses within a goitrous thyroid or surgical bed are difficult to discern. Thyroid nodules (particularly when posteriorly located) and cervical lymph nodes (especially within the tracheoesophageal groove) may mimic parathyroid pathology.⁶⁰

Figure 20-38. With dual-phase technetium 99m-MIBI imaging, an immediate anterior view of the neck reveals a focus of increased activity in the upper pole of the right thyroid lobe. On the 2-hour delayed image, the thyroid activity has washed out to a large degree; the persistent focus of increased activity in the upper right neck (*arrow*) was further confirmed on a 4.5-hour delayed scan, at which point there was additional thyroid washout. At surgery, a solitary parathyroid adenoma was resected.

Lymph nodes can sometimes be distinguished from parathyroid adenomas by a hyperechoic central fatty hilum and absence of the vascularity commonly seen with color Doppler imaging within parathyroid adenomas.⁷⁶ Thyroid nodules appear less vascular than parathyroid adenomas and more often demonstrate calcification, cystic changes, and heterogeneous echogenicity. A hyperechoic capsule favors a parathyroid adenoma. These sonographic features are inconsistent, however, and differentiating abnormal parathyroid glands from lymphadenopathy and thyroid masses is not always possible.

An advantage of CT is its ability to evaluate the entire neck and the mediastinum from the skull base to the aortic arch. Distinguishing lymphadenopathy from parathyroid adenomas with CT is problematic, as it is with ultrasonography. The use of CT requires the administration of IV contrast material, but only 25% of parathyroid adenomas enhance (Fig. 20–39).¹³⁵

CT evaluation of parathyroid adenomas may produce false-negative or false-positive results as a result of artifactual obscuration of parathyroid adenomas that may be caused by patient or respiratory motion, shoulder underpenetration or beam-hardening artifact, suboptimal technical factors, or inherently poor soft tissue differentiation. Identifying parathyroid adenomas may be especially challenging in the postoperative neck, where normal tissue planes are distorted and metallic clips generate streak artifact.

MRI evaluation of the neck employs standard T1-weighted, T2-weighted, and postcontrast T1-weighted imaging. Normal parathyroid glands are not visualized by MRI.⁶⁰ Parathyroid adenomas and parathyroid hyperplasia are typically bright on T2-weighted images, show soft tissue signal intensity on T1-weighted images, and enhance with contrast material; however, approximately 40% of abnormal glands have atypical MRI signal characteristics.^{42, 51, 56, 60, 61, 90, 102, 121, 134}

Pathologic parathyroid glands may contain fat, hemorrhage, sclerosis, or fibrosis, which may alter the expected MRI signal intensity.^{60, 61} Contrast-enhanced T1-weighted images should be performed with fat suppression to allow the enhancing adenoma to be differentiated from dark neck

fat.^{32, 48} MRI features are not specific for parathyroid adenomas, however, and cannot differentiate adenomas from other neck masses and lymphadenopathy.^{60, 79, 90, 137}

High-resolution MRI scanning is currently performed with surface coils, which may have a limited region of coverage. Multiple surface coils may be necessary to evaluate the neck together with the upper mediastinum. MRI is also susceptible to artifact degradation, particularly from patient and respiratory motion, flowing blood, or cerebrospinal fluid pulsation.

Several different imaging modalities may be combined to improve the sensitivity and specificity of parathyroid adenoma and hyperplastic gland identification in the virgin neck, the previously operated neck, and in ectopic locations.⁶¹ MRI is particularly useful for identifying abnormal ectopic parathyroid glands.^{51, 60, 61, 79, 137}

Fine-needle biopsy employing ultrasonographic, CT, or MRI guidance may be used to sample parathyroid gland enlargement.^{114, 128, 129} Cytology, immunocytochemistry, and radioimmunoassay for parathyroid hormone (PTH) may be conducted to evaluate the aspirated material.

Pathologic Parathyroid Conditions

Hyperparathyroidism

Hyperparathyroidism is a common endocrinopathy manifested by hypercalcemia and elevated circulating levels of PTH, with or without associated urinary, cardiovascular, GI, skeletal, or psychiatric abnormalities.⁵⁴ The solitary parathyroid adenoma is most often found along the inferior pole of a thyroid lobe¹⁵⁸ and is responsible for primary hyperparathyroidism in 80% of patients.^{34, 35, 106, 144, 145} Hyperplastic parathyroid glands (10%), multiple parathyroid adenomas (2% to 5%), and parathyroid carcinoma (1%) make up the remainder.^{34, 35, 106, 144, 145, 147} In 10% to 20% of patients, parathyroid adenomas are ectopic in location.^{27, 35, 92, 106}

Therapy for primary hyperparathyroidism is usually surgical resection of the abnormal gland or glands, especially in view of growing evidence of adverse cardiac and skeletal effects of chronic hyperparathyroidism.^{39, 74, 136} The use of routine preoperative imaging for patients with uncomplicated primary hyperparathyroidism is controversial.^{10, 80, 111, 146} Some surgeons recommend no preoperative imaging of patients with hyperparathyroidism, reporting a 90% to 95% cure rate in previously unoperated patients.^{22, 109, 111, 117, 144} The success rate of finding a hyperplastic parathyroid gland or adenoma at surgery, however, is less than 70% if the pathologic parathyroid gland is in an ectopic location.^{81, 144, 158}

Some authors have justified routine preoperative imaging with claims of improving operative success rates, decreasing the risk of recurrent laryngeal nerve and normal parathyroid gland injury, and lowering cost, operating time, and blood loss.^{11, 18, 36, 64, 75, 113, 117} With the emergence of minimally invasive parathyroidectomy performed using local anesthesia and a hand-held gamma probe intraoperatively, preoperative radionuclide localization is becoming standard practice.⁹⁶ In addition, preoperative imaging can identify concomitant thyroid pathology in up to 50% of patients.^{29, 63, 108, 153}

Figure 20–39. Axial postcontrast CT at the level of the clavicles shows an enhancing parathyroid adenoma (arrow) in the right tracheoesophageal groove. Goitrous enlargement of the right lobe of the thyroid can be visualized (curved arrow).

Parathyroid Adenomas

The identification of parathyroid adenomas has been evaluated using multiple imaging modalities with a range of specificities and sensitivities. Ultrasonographic identification of parathyroid adenomas is reported to have a sensitivity of 64% and a specificity of 94%.^{76, 108} The detection rate significantly improves when the parathyroid adenomas are large.¹⁰⁸ At sonography, parathyroid adenomas are typically homogeneously hypoechoic, sometimes with a hyperechoic capsule (Fig. 20-40).^{36, 108, 135} Adenomas may be partially cystic or inhomogeneous with foci of hypoechogenicity or hyperechogenicity.

Color Doppler imaging reveals parathyroid adenomas to be uniformly hypervascular, which may help distinguish them from other neck masses.⁷⁶

CT is reported to have a sensitivity of 70% and a specificity of 90% for parathyroid adenoma detection.¹³⁵ MRI has accuracy and sensitivity rates of 74% to 92% for identifying parathyroid adenomas (Fig. 20-41).^{61, 79, 134, 137} ^{99m}Tc-MIBI imaging has a reported sensitivity rate of 82% to 100% and is generally considered the standard initial imaging modality to identify a parathyroid adenoma.^{18, 36, 61, 77, 84, 99, 100, 140} It can detect not only the typical cervical single adenoma or rare dual adenomas but also ectopic and mediastinal adenomas (Fig. 20-42).

The fusion of metabolic sestamibi SPECT images with CT images offers optimized localization of a mediastinal adenoma for surgical planning and guidance, with or without the use of an intraoperative handheld gamma probe. Concomitant benign or malignant thyroid abnormalities (e.g., thyroid adenomas) may cause increased uptake of

Figure 20-40. Parathyroid adenoma. Transverse sonographic image shows a hypoechoic mass (arrow) inferior to the right lobe of the thyroid (asterisk). A, right common carotid artery.

^{99m}Tc-MIBI and lead to a false-positive scan.^{81, 87, 99, 100, 140}

Many of these false-positive results can be reduced by the use of subtraction techniques with ¹²³I.⁴⁹

Patients who are not candidates for surgical resection of parathyroid adenomas may be treated with percutaneous alcohol injection using ultrasonographic, CT, or MRI guidance.¹⁴⁸ This is a minimally invasive procedure with few risks if care is taken to avoid vascular structures during needle puncture. With a 22-gauge needle, 0.5 to 1 mL of 98% dehydrated alcohol is injected in multiple locations in the adenoma. Monitoring of serum calcium levels indicates success of the technique, and repeated percutaneous alcohol injections may be performed if necessary.

Parathyroid Hyperplasia

Parathyroid hyperplasia may be primary, secondary, or tertiary. Secondary and tertiary hyperparathyroidism are caused by chronic renal failure and are complicated by a variable degree of associated renal osteodystrophy. ^{99m}Tc-MIBI scanning is the imaging examination of choice to evaluate secondary and tertiary hyperparathyroidism, although only a minority of these patients require preoperative imaging. It is also the preferred imaging study for parathyroid hyperplasia evaluation, with a reported detection rate as high as 75% (Fig. 20-43).^{34, 36, 61, 77, 92, 99, 100, 106, 140} False-negative MIBI results therefore occur in at least 25% of cases. Ultrasonography has been reported to have a sensitivity rate of 30% to 69%, CT 45% to 88%, and MRI 40% to 74%.^{34, 35, 61, 79, 102, 106, 135, 137} Some hyperplastic parathyroid glands may calcify.¹²⁸ Imaging cannot differentiate parathyroid hyperplasia from parathyroid adenomas, and no modality typically identifies all four parathyroid glands.

Patients who are not surgical candidates may be treated by percutaneous alcohol ablation of hyperplastic parathyroid glands with the use of image guidance techniques similar to those used for adenoma reduction.^{128, 129}

In approximately 30% of patients, primary parathyroid hyperplasia is familial rather than sporadic, a component of MEN syndrome. MEN-1, also termed *Wermer's syndrome*, is an autosomal dominant disorder with high penetrance. The locus for this genetic syndrome is on chromosome 11. In addition to primary parathyroid hyperplasia, patients with MEN-1 have pancreatic islet cell tumors such as insulinomas, gastrinomas (Zollinger-Ellison syndrome), pancreatic polypeptide-producing tumors, glucagonomas, or vasoactive intestinal peptide tumors (VIPomas), and pituitary adenomas. Thyroid disorders, including goiter, adenomas, or thyroiditis; adrenal adenomas or carcinomas; and carcinoid tumors have also been reported. Parathyroid hyperplasia is also a component of MEN-2A and, occasionally, MEN-2B (or MEN-3) syndrome (see earlier discussion of medullary thyroid carcinoma).

Persistent or Recurrent Hyperparathyroidism

Persistent or recurrent hyperparathyroidism after attempted surgical cure presents a serious challenge. In approximately 50% of cases, reoperation reveals abnormal parathyroid glands in a perithyroidal location that were missed at the initial surgery.^{22, 80, 110} Other parathyroid ade-

Figure 20-41. Surgically proven parathyroid adenoma. *A*, Axial T2-weighted MR image shows an ovoid mass (arrow) of increased T2-weighted signal posterior to the right lobe of the thyroid and adjacent to the esophagus (asterisk). *B*, Axial T1-weighted MR image demonstrates that the mass (arrow) is isointense to thyroid parenchyma. Flow voids can be seen in the right common carotid artery (asterisk) and right internal jugular vein (open arrow). *C*, Axial T1-weighted MR image after gadolinium contrast administration demonstrates enhancement within the lesion (arrow). *D*, Axial postcontrast CT image shows a homogeneously enhancing ovoid mass (arrow) in the right tracheoesophageal groove.

Figure 20-42. *A*, An anterior image of the neck and thorax immediately following technetium 99m-MIBI injection demonstrates physiologic thyroid activity (curved arrow) with a single focus of increased activity in the chest to the left of midline (arrow). *B*, Most of the thyroid activity has faded by 2 hours on the delayed images, thus accentuating the persistent mediastinal abnormality (arrow). At surgery, a mediastinal parathyroid adenoma was resected, resulting in postoperative eucalcemia.

Figure 20-43. Dual-phase technetium-99m-MIBI imaging—immediate (A) and 2-hour-delayed (B) acquisitions—of a patient with chronic renal failure. Imaging reveals four persistent foci of increased activity on the delayed images (B), consistent with parathyroid hyperplasia.

noma locations, however, include the anterior mediastinum, deep in the tracheoesophageal groove, and deep cervical, intrathyroidal, and parathymic locations.^{60, 80, 82, 110} Imaging can assist the surgeon in preoperatively identifying a persistent or ectopic parathyroid adenoma or parathyroid hyperplasia, increasing surgical success from 60% to 90%.^{61, 79, 106}

^{99m}Tc-MIBI imaging is the mainstay for identifying the source of persistent hyperparathyroidism; it has a sensitivity of 80% to 90% (Fig. 20-44).^{61, 62, 73, 77, 150} Persistent postoperative thyroid MIBI uptake due to suspected thyroiditis may obscure residual parathyroid adenoma or hyperplasia.³⁶ Ultrasonography, CT, and MRI have variable sensitivities of between 25% and 90% for the detection of residual parathyroid tissue.^{42, 51, 57, 61, 79, 81, 102, 135} Some au-

thors recommend MRI as a complementary imaging modality to ^{99m}Tc-MIBI scintigraphy.^{24, 98}

Although the success of ¹⁸FDG PET imaging of parathyroid adenomas has been variable, carbon 11 (¹¹C) methionine PET imaging is reported to be more successful than CT or ultrasonography in patients requiring either primary or reoperative resection.^{94, 138} In the patient with persistent or recurrent hyperparathyroidism, most investigators recommend initial functional imaging with ^{99m}Tc-MIBI, complemented by anatomic imaging with MRI or CT; ultrasonography plays a limited role in these patients.⁹⁸ ¹⁸FDG or ¹¹C-methionine PET may be attempted in patients without localization after ^{99m}Tc-MIBI scintigraphy.

Other approaches include parathyroid venous sampling

Figure 20-44. A, Anterior projection of neck and upper chest from a technetium 99m-MIBI radionuclide scan in a patient with persistent hyperparathyroidism after thyroidectomy demonstrates a prominent focus of tracer uptake within the low right neck (arrow). Uptake within the thyroid parenchyma (arrowheads) is mild. B, Axial postcontrast CT scan through the lower neck in the same patient demonstrates an enhancing right paratracheal soft tissue mass (arrow), found to be a parathyroid adenoma at reoperation.

Figure 20-45. Digital subtraction angiographic image in AP projection. Left superior thyroidal artery injection shows a homogeneously enhancing mass consistent with a parathyroid adenoma (arrow) within the low left neck. (Courtesy of M. Mazer, M. D.)

and arteriography (Fig. 20-45).²⁰ These invasive procedures have sensitivities of 50% to 80%^{24, 82} but may be valuable in selective cases, particularly in previously operated patients who have fibrotic scar tissue, abnormal tissue planes, postoperative inflammation, or enlarged reactive lymph nodes, which may lead to false-negative or false-positive results with other imaging studies.

Other Parathyroid Masses

Parathyroid Cysts

Parathyroid cysts are rare, comprising only 0.6% of all thyroid and parathyroid lesions,¹⁵⁹ but they may be large at presentation. Most present in middle-aged women.⁶⁸ Parathyroid cysts may develop from pharyngeal pouch remnants or may represent degenerated parathyroid adenomas.¹⁵⁸ Almost all are found caudal to the inferior margin of the thyroid, and most are associated with the inferior parathyroid glands.¹⁵⁹ Mimics include thyroid or thymic cysts and necrotic lymph nodes.⁷¹

Symptoms may be secondary to tracheal, esophageal, or laryngeal nerve compression or from cyst hemorrhage and subsequent pain.¹⁵⁹ Ultrasonography demonstrates an anechoic mass in a typical parathyroid gland location. CT demonstrates a well-circumscribed, low-density parathyroidal mass. MRI may demonstrate bright signal intensity on T1-weighted images if the contents of the cyst have an increased protein content or hemorrhage. ^{99m}Tc-MIBI may demonstrate a photopenic focus. Fine-needle aspiration

yields a characteristic clear watery fluid with high PTH and low thyroglobulin content and may be curative if combined with a sclerosing agent.¹⁴

Parathyroid Carcinoma

Parathyroid carcinoma is a rare cause of hyperparathyroidism, with an incidence of 1% to 2% and no sex preference.¹⁵⁹ Thirty percent of patients present with metastatic lymphadenopathy; distant metastases are seen in approximately 25%.¹⁵⁹ Approximately 90% of parathyroid carcinomas cause hyperparathyroidism.^{67, 68} Parathyroid carcinomas are indistinguishable from parathyroid adenomas in all imaging studies except when local invasion of neighboring structures is present.²³ ^{99m}Tc-MIBI and ¹⁸F-DG PET may be used to detect local and distant metastases.^{55, 73, 94}

Pediatric Head and Neck Imaging

John C. Egelhoff

Head and neck pathology in children encompasses diseases that are both unique to the pediatric age group as well as processes that occur in adults. The diseases that cross age barriers may have a different biologic behavior pattern or clinical presentation when they occur in children. Fortunately, most pediatric head and neck pathology is composed of benign tumors, congenital masses, and inflammatory lesions. In contrast to the situation with adults, primary malignancies are a less frequent occurrence in children. To approach the imaging algorithms and differential diagnoses in a logical method, imaging specialists should have a basic knowledge and understanding of the pathology that occurs in the head and neck in children.

The topic of the head and neck pathology in children represents a vast spectrum of diseases. This chapter focuses on extracranial disease processes of the head and neck, specifically the most common congenital masses, benign and malignant tumors, neurogenic masses, vasoformative lesions, and masslike conditions, including inflammatory processes related to adenitis. Additional topics in head and neck pathology are presented in other chapters.

Imaging

The imaging modality of choice in children with head and neck pathology depends on the clinical findings, the patient's age, and the location of the mass. Generally, the initial imaging study in the young child is sonography. The ability to perform this examination without giving sedation and the lack of ionizing radiation are primary advantages. Sonography is excellent in differentiating solid from cystic masses and is useful in defining the location and extent of these masses. Ultrasound may be helpful in the differentiation of phlegmon from abscess in cases of suppurative adenitis. Color-flow Doppler imaging can be used to assess vascular patency when masses involve the vascular bundle and to demonstrate the appearance of intralesional and perilesional vascularity.

Computed tomography (CT) enables an accurate diagnosis in most cases of extracranial head and neck pathology in children. In addition to the obvious advantage of evaluating bony involvement, CT can assess the location and extent of masses, the internal attenuation values and enhancement characteristics, and the relationship of masses to critical adjacent structures. The full extent of masses and inflammatory processes is better delineated by CT compared with sonography. With newer scanners, multiplanar reconstruction (MPR) is helpful in further defining

pathology. The speed of the new multidetector scanners should significantly decrease the need for sedation in the pediatric patient. In our experience, CT is the mainstay of imaging of pediatric head and neck pathology because of the speed and ease of the study as well as the useful diagnostic information obtained for the clinician.

Magnetic resonance imaging (MRI), with its multiplanar capabilities, is very helpful in the evaluation of skull base masses for the detection of intracranial extension. Flow-sensitive techniques and magnetic resonance angiography (MRA) are useful in assessing involvement of the vascular bundle by tumor, vascular patency, and, in rare cases, intralesional vascularity. In some cases, soft tissue signal characteristics of tumors on MRI give a more definitive diagnosis. In our experience, MRI is usually reserved as a secondary study because of the longer imaging time, necessitating the need for additional sedation; this liability also dictates the need for dedicated nursing support and monitoring equipment, which may not be available at all facilities.

Conventional angiography is used primarily in the evaluation of vascular masses that are potentially amenable to embolization. Embolization can be used as a primary means of therapy in lesions such as vasoformative masses or as an adjunctive treatment before surgery in lesions such as juvenile nasopharyngeal angiofibroma.

Congenital Masses of the Neck

The most common benign congenital masses of the neck in children include thyroglossal duct cysts (72%) and anomalies of the branchial apparatus (24%). Thymic cysts, dermoid and epidermoid cysts, and teratomas are less common congenital masses of the head and neck in the pediatric age group.¹⁹¹

Thyroglossal Duct Cyst

Thyroglossal duct cysts (TDCs) are the second most common benign cervical mass in children after reactive lymphadenopathy,^{177,242} comprising approximately 70% of congenital neck masses in children.²⁴⁴ At approximately 3 weeks of gestation, the thyroid gland begins to develop as a midline endodermal diverticulum from the floor of the pharynx, between the tuberculum impar and copula. Over the following 4 weeks of embryonic development, the primitive thyroid gland enlarges to form a bilobed divertic-

ulum that will descend caudally along the epithelial-lined thyroglossal duct. This duct extends from the foramen cecum at the tongue base (at the junction of the anterior two thirds and posterior one third of the tongue) to the lower neck (at the future location of the pyramidal lobe of the thyroid gland).

As the diverticulum descends, it remains ventral to all arch derivatives caudal to the first arch. Thus, the path of the primitive thyroid gland courses over the anterior and inferior aspects of the hyoid bone (with a small posterior loop behind the hyoid), thyroid cartilage, and cricoid cartilage. Caudal migration leaves a connecting tract (thyroglossal duct) between the foramen cecum and pyramidal lobe of the thyroid gland. In the usual course of events, the duct involutes between 8 and 10 weeks of gestation. Thyroglossal duct cysts or fistula form when any part of the duct fails to involute, thus leaving functioning secretory epithelium behind.^{97, 191, 244}

Thyroglossal duct cysts usually present in the first 5 years of life, with approximately 66% noted before age 7 years. Males and females are equally affected. The cysts are more commonly found in Caucasians.⁵ Unless infection is a complicating factor, patients with thyroglossal duct cysts typically present with a nontender, mobile, 2- to 4-cm, subcutaneous midline neck mass of variable firmness. Occasionally, there is a history of fluctuating size; more commonly, however, the cyst demonstrates an abrupt or gradual increase in size with time. Complications of infection, fistula formation, or rupture of the mass can also lead to clinical presentation.^{97, 229} Fistulous openings are almost always secondary to infection associated with spontaneous or surgical drainage.⁵ Coexisting carcinoma in the wall of the cyst is reported in fewer than 1% of patients with TDC. This typically occurs in adults and is thyroid in origin.^{5, 19, 34, 45}

Microscopically, TDC is lined by simple columnar or squamous epithelium. Infrequently, inflammatory changes can distort the usual mucosal findings with variable amounts of fibrous tissue in the cyst wall. This usually

forces the pathologist to make a presumptive diagnosis based on clinical and surgical evidence. Thyroid tissue is uncommonly found in the wall of the cyst, accounting for the rare occurrence of thyroid carcinoma.^{97, 177, 242}

Thyroglossal duct cysts are classified by location as follows: infrahyoid (65%), suprahyoid (20%), and at the level of the hyoid (15%).^{20, 164, 193, 244} Initial imaging evaluation is often performed with ultrasound, which demonstrates a well-defined, thin-walled, midline, or paramedian mass with increased through transmission and variable internal echogenicity. Infected cysts typically have a thicker wall with variable increased internal echogenicity. Thus, the pattern of internal echogenicity in these cysts may not be helpful in distinguishing infected from noninfected lesions.^{141, 253} TDC appears as a mass of relatively decreased attenuation to muscle with variable rim enhancement on CT (Fig. 21-1). Cysts below the level of the hyoid are almost always embedded in the strap muscle.¹⁹³ Infection or hemorrhage alters these imaging characteristics¹⁹³ (Fig. 21-1). The primary differential considerations by imaging include: dermoid and epidermoid cysts, branchial cleft cysts (if TDC is paramedian in location), or rarely, sebaceous cysts.¹⁷⁷

Historically, preoperative nuclear medicine imaging of the thyroid was performed to document normal functioning thyroid tissue, because the only functioning tissue was occasionally located within the thyroglossal duct cyst.¹⁸⁶ More recently, reports indicate that preoperative identification of a normal thyroid gland by ultrasound confirms the presence of a source of thyroid hormone separate from the thyroglossal duct cyst, precluding additional imaging studies.¹⁴¹

The treatment (the Sistrunk procedure) is surgical, with removal of all tissue along the course of the duct as far as the foramen cecum. Removal of the central portion of the hyoid bone as well as the tract coursing behind the hyoid has led to a decreased rate of recurrence (~3% to 5%).^{177, 229}

Figure 21-1. Thyroglossal duct cyst. A, Axial postcontrast CT scan demonstrates a midline mass of decreased attenuation (arrows) at the level of the thyroid gland. Minimal rim enhancement is present. B, Coronal fast spin-echo (FSE) MRI scan shows an oval-shaped mass of slightly hyperintense signal at the base of the tongue, in the area of the foramen cecum (arrowhead) in this infected cyst.

Anomalies of the Branchial Apparatus

A basic knowledge of the normal embryogenesis of the branchial apparatus and the derivatives is helpful in the understanding the imaging appearance of these anomalies.^{142, 148, 191, 223} The branchial apparatus is a complex structure derived from neural crest cells. It develops between the 2nd and 7th weeks of gestation. This embryonic structure can be subdivided into five pairs of mesodermal arches that lie between five paired ectodermal branchial clefts (grooves) externally and four endodermal pharyngeal pouches internally.¹⁴⁸ The fifth arch lies buried near the site of the laryngotracheal outgrowth and by convention is called the sixth arch. These are the primitive structures that give rise to the muscles, bones, and ligaments of the face and neck as well as their nerve and blood supply.¹⁹¹

After 4 weeks of gestation, at which time the branchial arches are well defined, the first and second arches begin to thicken and enlarge. This thickening and enlargement of the first and second arches joins with the third and fourth arches and their intervening closing membranes to form a shallow ectodermal pit called the cervical sinus of His. The second and fifth clefts then merge with each other, obliterating the cervical sinus. The first and second pouches merge to form the tubotympanic recess that further develops into the middle ear and eustachian tube. The ventral portion of the second branchial pouch gives rise to the tonsillar fossa. The inferior parathyroid, thymus, and piriform sinus are formed by the third pouch and the superior parathyroid gland and apex of the piriform sinus by the fourth pouch. The first branchial cleft is the only cleft to give rise to an adult structure, the epithelium of the external auditory canal.¹⁶⁵

Although the cause of branchial anomalies is controversial, current theories include (1) an origin as *vestigial remnants* secondary to incomplete obliteration of the branchial apparatus and (2) structures that arise from "buried" epithelial *cell rests*. In the vestigial remnant theory, incomplete obliteration of any portion of a branchial cleft, pouch, or the cervical sinus of His can lead to formation of a sinus, fistula, or cyst. In the cell rest theory, trapped cells located anywhere in the branchial apparatus are thought to be capable of forming branchial cysts later in life.^{24, 148}

Anomalies of the branchial apparatus are classified as fistula, sinus, or cyst. If there is persistence of both a branchial cleft and a corresponding pharyngeal pouch, a communication in the form of a fistula can develop. In this case, an epithelium-lined tract connects the skin to the lumen of the foregut (pharyngeal mucosa). A branchial sinus is an incomplete tract that usually opens externally to the lateral skin surface of the neck. Communication with an associated cyst is variable. Both fistulas and sinuses can be lined by squamous, ciliated, or columnar epithelium. Congenital cysts of branchial origin have no internal or external communication with the skin or pharynx. The cysts are thin-walled and lined with squamous or columnar epithelium.^{24, 148}

First Branchial Anomalies

First branchial apparatus anomalies account for 5% to 8% of all branchial anomalies, and are usually in the form

of a cyst or sinus.⁹⁵ Although both Arnot^{9a} and Work²⁶⁰ attempted to classify first branchial anomalies into two distinct subtypes, Olsen found this scheme difficult in the categorization of all first branchial anomalies.^{77, 180} An understanding of these anomalies is not intuitive; thus, a grasp of the regional embryology appears to be more helpful rather than an attempt to subclassify them.

The first branchial apparatus gives rise to portions of the middle ear, external auditory canal, eustachian tube, mandible, and maxilla. The formation of these structures is completed by 6 and 7 weeks of gestation. The parotid gland and facial nerve form and migrate between 6 and 8 weeks of gestation. First branchial apparatus anomalies present in a variable relationship to the parotid gland and facial nerve. They can arise anywhere along the nasopharynx, middle ear cavity, external auditory canal, superficial or deep lobes of the parotid gland, superficial to the parotid gland, angle of the mandible, or anterior or posterior to the pinna.²⁴

Although this anomaly occurs in childhood, it is more commonly encountered in middle-aged women who present with recurrent abscesses or inflammatory processes at the angle of the mandible or ear. If the anomaly is related to the parotid gland, the patient often presents with recurrent parotid abscesses, which are unresponsive to therapy. Refractory cases, associated with facial nerve palsy, can mimic a parotid neoplasm clinically.²⁴² If the cyst drains into the external auditory canal, the initial presentation may be otorrhea.

On ultrasound, CT, and MRI, a first branchial cyst appears as a typical cystic mass that may be located within, superficial, or deep to the parotid gland and near the external canal of the ear or angle of the mandible (Fig. 21-2). Infected cysts have variable wall thickness and enhancement characteristics. When the anomaly is located in the parotid gland, imaging findings are nonspecific and do not allow this mass to be differentiated from other cystic masses of the parotid gland.¹²⁷

Second Branchial Anomalies

Approximately 95% of all branchial anomalies are related to the second branchial apparatus. The most common

Figure 21-2. First branchial apparatus cyst. Axial postcontrast CT scan. A nonenhancing, kidney-shaped mass is seen superficial to, but contiguous with, the parotid gland (curved arrow).

location of this anomaly is the submandibular space; however, occurrence may be anywhere from the oropharyngeal fossa to the supraclavicular region of the neck.¹²⁷ Three fourths of these anomalies are cysts.¹²⁷ Fistulas or sinuses usually present before age 10 years, whereas cysts are more common between ages 10 and 40 years.^{158, 231} There is no gender predilection.⁶⁷

Bailey classified second branchial cysts into four subtypes based on location^{12, 162, 175, 215}:

Type I cysts lie deep to the platysma muscle and the overlying cervical fascia, and anterior to the sternocleidomastoid muscle. These cysts are thought to represent a remnant of the tract between the sinus of His and skin.

Type II cysts, thought to be the result of persistence of the sinus of His, are the most common. They are located posterior to the submandibular gland, anterior and medial to the sternocleidomastoid muscle and anterior and lateral to the carotid space.

Type III cysts course medially, between the internal and external carotid arteries, and may extend to the lateral wall of the pharynx or skull base. These cysts are thought to arise from a dilated pharyngeal pouch.

Type IV cysts arise from a remnant of the pharyngeal pouch and lie in the mucosal space of the pharynx, adjacent to the pharyngeal wall.

Second branchial cleft cysts most commonly present as a fluctuant, nontender mass at the lateral aspect of the mandibular angle.^{162, 230, 231} If the cyst becomes infected, patients seek medical attention with a clinical history of a slowly enlarging, painful mass.²³¹ If a fistula is present, an ostium is usually noted at birth at the anterior border of the junction of the middle and inferior third of the sternocleidomastoid muscle. The associated tract courses deep to the platysma muscle, ascends laterally along the carotid sheath, and continues above and lateral to the hypoglossal and glossopharyngeal nerves. It then passes between the internal and external carotid arteries before terminating in the region of the palatine tonsillar fossa.^{12, 24}

Because these cysts usually present as a neck mass in the young child, sonography is often the initial imaging study. The cysts range in size from 1 to 10 cm.^{58, 243} If the anomaly is uncomplicated, the sonographic appearance is typical for a cyst (i.e., a sharply marginated, anechoic, compressible mass with increased through transmission).¹²⁷ A well-circumscribed, thin-walled mass of decreased attenuation is present on CT²³⁰ (Fig. 21-3). On MRI, the fluid within the cyst varies from hypointense to slightly hyperintense to muscle on T1-weighted images and is usually hyperintense to muscle on T2-weighted images.⁹⁵ When the cyst is infected, it can demonstrate increased echogenicity on a sonogram, relatively increased attenuation on a CT scan, and relatively hyperintense MRI signal, with variable contrast enhancement and edema of surrounding tissue.^{24, 95, 162, 168, 242} Occasionally, the "beak sign," pathognomonic of a Bailey type III second branchial cyst, is present. In this case, the medial aspect of the cyst is compressed and forms a beak as it extends between the internal and external carotid arteries on axial CT or MRI.⁹³

Third and Fourth Branchial Anomalies

Both third and fourth branchial anomalies are rare.⁴⁹ In spite of the rarity of third branchial cysts, they are the

Figure 21-3. Second branchial apparatus cyst. Axial postcontrast CT scan. A rounded, nonenhancing mass is present in the typical position of a Bailey type II cyst. The cyst lies posterior and lateral to the submandibular gland, anterior and medial to the sternocleidomastoid muscle, and lateral to the carotid space.

second most common congenital lesion of the posterior cervical space after lymphatic malformation.¹⁸³ Anomalies of the fourth branchial apparatus usually appear as a sinus rather than a cyst or fistula. The majority of third and fourth anomalies are found on the left.⁴⁹

Because the dorsal aorta between the third and fourth arches involutes, a third branchial apparatus anomaly originates in the posterior cervical space.²⁴ Third branchial cleft cysts must be located posterior to the common or internal carotid artery, and between the hypoglossal nerve (below) and glossopharyngeal nerve (above). If the anomaly is in the form of a fistula, it will have a cutaneous opening similar to a second branchial fistula (i.e., anterior to the lower sternocleidomastoid muscle). It then courses posterior to the common or internal carotid artery, anterior to the vagus nerve, and between the hypoglossal and glossopharyngeal nerves. The fistula pierces the thyrohyoid membrane and enters the piriform sinus anterior to the internal pharyngeal nerve.

A third branchial cleft cyst often presents as a painless, fluctuant mass in the posterior triangle of the neck after a viral upper respiratory infection. On imaging, the cyst most commonly appears as a unilocular mass with variable wall thickness and enhancement characteristics.¹²⁷

Fistulas of the fourth branchial apparatus have not been reported.⁴⁹ Anomalies related to the fourth branchial cleft are in the form of a sinus tract. The tract arises from the piriform sinus and pierces the thyrohyoid membrane. It then descends along the tracheoesophageal groove and continues into the mediastinum, following a course under the aortic arch on the left and ascending into the neck, anterior to the common or internal carotid artery. This is in contrast to third branchial remnants, which course posterior to the carotid artery (Fig. 21-4). Rarely, the tract may descend on the right coursing under the subclavian artery.²⁴

Differentiating third from fourth branchial anomalies on

Figure 21-4. Fourth branchial apparatus sinus. Axial noncontrast CT after the patient had ingested oral contrast medium. Barium is present in a sinus tract (arrow) that lies anterior to the thyroid gland on the left. The tract arose from the piriform sinus and continued into the mediastinum.

imaging is problematic. Key relationships include the carotid artery and the superior laryngeal nerve. Third branchial anomalies lie posterior to the carotid artery, whereas fourth branchial anomalies are anterior to it. Those anomalies above the superior laryngeal nerve are third branchial origin, whereas those below the nerve are related to the fourth branchial apparatus.⁴⁹ On imaging, both third and fourth branchial anomalies related to the piriform sinus may appear similar to external laryngoceles.²⁴

Cervical Thymic Remnants

Cervical thymic remnants are rare lesions derived from the third and fourth pharyngeal pouches. During the 6th week of gestation, thymic primordia (endoderm) develops from lateral and ventral diverticula of the third pharyngeal pouch, with a small contribution from the fourth pharyngeal pouch. These hollow outgrowths, which are connected to the pharynx by the thymopharyngeal ducts, begin to elongate in a caudal plane. At the end of the 6th week, the diverticula are obliterated secondary to epithelial proliferation. These two solid masses join in the midline before their final descent into the anterior mediastinum at the 9th week of gestation. In the 10th week of gestation, lymphocytes invade the endodermal structure to form lymphoid tissue in the thymus. The superior thymic primordia usually regress.^{17, 256}

Currently, two main theories have been reported to explain the etiology of thymic remnants. The *congenital theory*, favored by the most authorities, states that these cysts arise secondary to persistence of thymopharyngeal duct remnants. Progressive, cystic degeneration of thymic (Hassall's) corpuscles, primitive endodermal cells, lymphocytes, and the epithelial reticulum of the thymus have been proposed as the origin in the *acquired theory*.^{15, 65, 266} As related to the embryologic development, these cysts may be located beneath or medial to the sternocleidomastoid

and anywhere from the level of the hyoid to the superior mediastinum.¹⁷

Because the thymus reaches its greatest relative size at 2 to 4 years of age and its greatest absolute size at puberty, most thymic cysts are detected in childhood.⁸² Two thirds of thymic cysts are detected in the first decade of life (most commonly, at 3–8 years of age), with the remaining one third detected in the second and third decades.^{33, 93, 231, 256} Seventy-three percent of thymic cysts are found in **males**.^{33, 68, 160}

Most patients are asymptomatic, with 80% to 90% presenting with a slowly enlarging, painless neck mass near the thoracic inlet, anterior or deep to the sternocleidomastoid muscle.^{57, 65, 67, 68, 88, 160, 174, 254} Hoarseness, dysphasia, stridor, and dyspnea in the newborn may occasionally be seen as the initial complaint secondary to the mass effect. Infection, hemorrhage, or Valsalva maneuvers can cause rapid enlargement of the cyst.^{15, 174, 198, 231, 254} Seventy percent of thymic cysts are left-sided, 23% are right-sided, and the remaining 7% are midline or pharyngeal in location.^{15, 51}

Cervical thymic remnants may be found anywhere along the path of the thymopharyngeal duct, which courses along the carotid sheath, from the level of the angle of the mandible to the superior mediastinum. The lesions vary in size (1 to 17 cm) and shape (round to elongated).^{15, 26, 33} Most cysts are unilocular and have a smooth lining.^{33, 65, 160, 191} A connection between the cervical thymic anomaly and the mediastinal thymic gland may persist in the form of direct extension or a remnant of the thymopharyngeal duct in 50% of cases.^{38, 52, 88, 247} A fibrous strand may also remain between the cervical thymic cyst and the thyroid gland.⁶⁵ Cervical thymic cysts are often associated with thyroid and parathyroid inclusion cysts.¹⁵

Grossly, thymic cysts are well defined, thin-walled, uniloculated, or multiloculated masses. They are lined by stratified or pseudostratified, cuboidal, or columnar epithelium with pathognomonic Hassall's corpuscles within the wall.^{15, 160} The wall may also contain lymphoid tissue or giant cells with cholesterol clefts and granulomas.^{38, 65, 68, 160}

Thymic tissue must be present within the lesion for the pathologic diagnosis. Occasionally, thyroid or parathyroid tissue is also found within the cyst or cyst wall.^{48, 247} As derivatives of the third and fourth branchial clefts, thymic cysts can extend through the thyrohyoid membrane and into the piriform sinus.⁶⁸ There have been no reports of malignant degeneration of thymic cysts in children or the development of myasthenia gravis or immunologic deficiencies following excision of a thymic cyst. However, malignant degeneration has been documented in ectopic solid thymic tissue.^{124, 174}

Because most ectopically located thymic masses are primarily cystic, sonography usually shows a large, well-defined unilocular or multilocular cyst parallel to the sternocleidomastoid muscle with hypoechogenicity and increased through-transmission. A homogeneous, near-water attenuation, uniloculated or multiloculated, nonenhancing mass is seen located along the course of the carotid sheath on CT^{26, 33, 114, 140, 161} (Fig. 21-5). MRI of thymic cysts demonstrates a fluid-filled mass with signal characteristics isointense to hyperintense to water.¹⁴⁹ If hemorrhage or infection is present, imaging characteristics vary accordingly.^{33, 231}

Figure 21-5. Thymic cyst. Axial postcontrast CT scan. A large, round, nonenhancing mass is present in a position similar to a second branchial apparatus cyst; however, the sternocleidomastoid muscle lies in a more lateral position.

The main differential consideration of thymic remnants is a second branchial cleft cyst. A true thymic cyst passes posterior to the carotid bifurcation and terminates in the piriform sinus, whereas a second branchial cleft cyst passes between the internal and external carotid arteries and ends in the superior tonsillar pillar. Fifty percent of cervical thymic cysts extend into the superior mediastinum, whereas mediastinal extension with branchial cleft anomalies does not occur.^{15,174} If a mass is located in the area of the inferior pole of the thyroid gland, a thymic origin should be considered.¹²⁵ Other differential considerations would include thyroglossal duct cyst, lymphatic malformation, cystic neuroblastoma, lymphadenopathy, external laryngocele, and vallecular cysts.^{33,114}

Dermoid and Epidermoid Cysts

The terminology and classification of dermoid, epidermoid, and teratoid cysts of the head and neck can lead to confusion because of overlapping features. All of these cysts can be considered in the spectrum of teratomas. The masses share a common feature of containing tissue that is foreign to the body part from which it originates. Dermoids and epidermoids are ectoderm-lined inclusion cysts, with dermoids containing skin appendages, and epidermoids lacking these elements. Teratoid cysts may be composed of tissues of other organ systems.¹⁰⁸

Dermoid cysts of the neck commonly occur near midline, along lines of embryonic fusion.¹¹⁹ In the neck, the most common location is the floor of the mouth, accounting for 11.5% of all dermoids.¹⁷³ Other locations in the head and neck include the anterior neck, tongue, and palate.^{172,173}

Epidermoid cysts are rarely found in the head and neck. When they occur, they are usually present in infancy.²³⁰ There is no gender predilection with dermoid or epidermoid cysts.^{104,231}

Dermoid cysts typically become clinically apparent in the second or third decades of life.^{104,231} They most commonly present as a soft, slowly growing, suprahyoid, midline neck mass. Size is variable, from a few millimeters to 12 cm. A rapid increase in size can be seen secondary to association with a sinus tract, pregnancy, or increasing desquamation of skin appendage products.^{182,230} Lesions lying in the floor of the mouth, in the sublingual space, are often clinically inapparent or exhibit minimal mass effect. If located in the submandibular space, the lesion usually presents with a more obvious swelling or mass effect.^{104,252} In contrast to thyroglossal duct cysts, which move with protrusion of the tongue because of their association with the hyoid bone, dermoid cysts are nonmobile with this maneuver.¹⁸²

On pathologic examination, dermoid cysts are well-defined, encapsulated masses lined with squamous epithelium. They may contain skin appendages in the form of sweat or sebaceous glands or hair follicles. Inclusion of skin appendages can lead to the formation of keratin and sebaceous material and, occasionally, hair.²²⁵ The incidence of malignant degeneration into squamous cell carcinoma is approximately 5%. Epidermoid cysts lack skin appendages but otherwise are similar in histologic appearance to dermoids.²³⁰

Because dermoid cysts typically present in older children, CT is often performed as the initial imaging study. Dermoid cysts appear as a thin-walled, unilocular mass with homogeneously decreased attenuation, with CT measurements in the negative numbers (0 to -18 HU)¹⁰⁸ (Fig. 21-6). Occasionally, a "sac of marbles" appearance, representing multiple, small fatty nodules within the fluid, is seen within the cyst. This appearance is virtually pathognomonic of a dermoid cyst. A more heterogeneous appearance can be present secondary to a difference in composition of the various skin appendage components. Fluid-fluid levels are a rare finding. After administration of contrast medium, thin, peripheral enhancement is often present.²³⁰ On MRI, signal changes are variable and dependent on the composition of the cyst. T1-weighted signal can be hyperintense secondary to lipid concentration or isointense to muscle; T2 signal is usually hyperintense to muscle.^{104,252}

When dermoids are located in the floor of the mouth, accurate localization by imaging is important for surgical planning. Most commonly, dermoids in the floor of the mouth lie above the mylohyoid muscle, which places them in the sublingual space. These cysts are amenable to an intraoral surgical approach. Cysts that lie below the mylohyoid muscle are localized to the submandibular space, necessitating an external, submandibular approach. Coronal CT or MRI is the optimal imaging plane for localization of these masses into the appropriate space.²³⁰

Epidermoid cysts most commonly have homogeneously decreased attenuation on CT, with hypointense T1-weighted and hyperintense T2-weighted signal to muscle on MRI closely following water signal. With this imaging appearance, it is difficult to distinguish epidermoid cyst

Figure 21-6. Dermoid cyst. Axial postcontrast CT scan. A well-defined mass of decreased attenuation lies in the anterior neck, slightly off midline (*curved arrow*). Attenuation values were 0 to -5 Hounsfield units (HU).

from uncomplicated cystic lesions in the floor of the mouth, such as a lymphatic malformation or ranula.⁴⁸

Teratoma

Teratomas constitute approximately 9% of all pediatric head and neck neoplasms, with fewer than 5% of all teratomas occurring in the head and neck.^{9, 47, 115} In the pediatric population, most teratomas are extragonadal in location, with 82% found in the sacrococcygeal area.^{14, 240} Locations in the head and neck include the neck, orbit, nasal cavity, paranasal sinus, oral cavity, oropharynx, nasopharynx, temporal bone, and ear.^{1, 60, 97, 132, 239} Teratomas are thought to arise from misplaced, pluripotent, primordial germ cells. They are classified as “true neoplasms” because of their biologic behavior of progressive and invasive growth patterns.²⁰⁰

Teratomas have been subclassified by Ewing and Arnold into four types^{66a, 203}:

1. *Dermoids*—masses of ectodermal and mesodermal elements, composed mostly of adipose tissue with fragments of muscle, cartilage, or bone.
2. *Teratoids*—masses containing elements of all three germ layers, differing from true teratomas because of their poor histologic differentiation.
3. *True teratomas*—masses containing elements of all

three germ layers, with differentiation to enable recognizable organs by histologic examination.

4. *Epignathi*—masses containing elements of all three germ layers, with differentiation greater than true teratoma, usually incompatible with life.

Cervical Teratoma

Grossly, cervical teratomas are encapsulated, partially cystic masses with a variegated appearance on cut section. These tumors contain diverse histopathologic findings with variable degrees of maturation. Mature elements are derived from ectoderm, mesoderm, and endoderm; immature tissue arises mostly from neuroectoderm. Neuroectodermal elements (both mature and immature) tend to predominate in cervical teratomas. Although cells in this tumor can be found in any stage of differentiation, the degree of histologic maturity should not be equated with malignant potential.^{9, 66a}

Clinically, teratomas are divided into (1) those present at birth or in early childhood and (2) those presenting in the first decade of life. The clinical presentation is variable and depends on the size and location of the tumor. Congenital tumors (presenting in the first 60 days of life) tend to have a benign clinical behavior, but they exhibit a high mortality rate secondary to airway compression with pulmonary compromise. Tumors that present later are usually smaller but carry a higher incidence of malignancy.²⁰⁰ True cervical teratomas are large and can lead to obstetric complications, such as difficult labor with malpresentation, premature labor, stillbirth, and acute respiratory distress.³⁵ Extensive unilateral or more diffuse cervical swelling is often present.^{222, 228} Maternal polyhydramnios has been reported in 18% of patients with cervical teratomas.^{99, 197, 201}

Because of the frequent use of ultrasonography in obstetrics, the diagnosis is often made antenatally. On sonograms, teratomas demonstrate heterogeneous echogenicity with multiloculated areas of cystic and solid regions, angulated cyst walls, and acoustic shadowing from calcifications. The mass may appear well defined or, less commonly, infiltrative.²⁰⁰ After birth, the patients are usually referred for CT.

Imaging characteristics directly reflect the pathologic makeup of the tumor, often demonstrating a heterogeneous attenuation pattern and appearing primarily cystic, solid, or multicystic. Most cervical teratomas are large, measuring up to 12 cm in size, with approximately 50% containing calcification^{200, 258} (Fig. 21-7). Both CT and MRI are helpful in delineating the extent of the tumor and the degree of airway compromise.¹⁰⁵ The MRI appearance is a mass of heterogeneous signal on all pulse sequences with the fatty component, hyperintense on T1-weighted sequences, and areas of calcification, hypointense or hyperintense on T1-weighted images. Attenuation values and signal characteristics of fat and bone, in a mass of the head and neck in a young child, is nearly pathognomonic of teratoma. Variable enhancement is present on both CT and MRI after contrast administration. Intubation is commonly required in these patients before scanning.²⁰⁰

The primary differential consideration of a cervical teratoma is lymphatic malformation, which more closely follows water signal on all pulse sequences on MRI. Other

Figure 21-7. Cervical teratoma. Axial postcontrast CT scan. The majority of the anterior neck is involved with an extremely large, heterogeneous mass with mild enhancement. The vascular bundle on the right is not visualized secondary to tumor involvement. The infant required intubation because of mass effect on the airway.

differential considerations include thyroglossal duct cyst, branchial cleft cyst, goiter, hemangioma, and external laryngocele.⁵⁷

Despite the appearance of teratomas on CT and MR, cervical teratomas do not typically infiltrate surrounding tissue; thus, complete surgical resection is usually possible.²⁰⁰ Surgery is mandatory for congenital cervical teratomas, as the mortality rate is 80% to 100% secondary to airway complications, if the tumor is left untreated. Thus, differentiating this tumor from other congenital space-occupying masses of the neck is crucial. The incidence of true malignancy of congenital teratoma is low (<5%), associated anomalies are uncommon, and the prognosis with surgery is excellent.^{90, 187}

Congenital Nasal Masses

Nasopharyngeal Teratoma

Greater than 50% of nasopharyngeal teratomas are seen in the first year of life, with nearly all true tridermal tumors present at birth.²⁵⁵ They usually arise from the superior or lateral wall of the nasopharynx. For teratomas in the nasal cavity, there is a predilection for girls.⁸⁷ The typical clinical presentation involves a neonate with severe respiratory distress, stridor, and dysphagia. These tumors can attain a large size and protrude from the mouth or nostrils.^{21, 222, 228}

The imaging appearance is similar to that of the cervical teratoma (Fig. 21-8). In addition to airway evaluation and evidence of vascular involvement, MRI is helpful in excluding intracranial extension.²⁵⁸ Differential considerations for nasopharyngeal teratoma include dermoid, encephalocele, nasal glioma, rhabdomyosarcoma, hemangioma, lipoma, neurofibroma, and lymphoma.²²⁶

Nasal Dermoid

Nasal dermoids are thought to result from a lack of regression of a diverticulum of dura that extends through

the foramen cecum between the developing nasal cartilage and nasal bone.^{16, 184, 209} Depending on the patency of the diverticulum and its contents, the resultant lesion can be a dermal sinus, dermoid cyst, nasal glioma, or encephalocele.¹⁸⁴ Nasal dermoid cysts and dermal sinuses make up 3.7 to 12.6% of all dermoids of the head and neck.^{179, 209}

Most nasal dermoids are sporadic in nature; however, several familial cases have been reported.^{27, 167} Nasal dermoid cysts and dermoid sinuses can present at any age but are most commonly found in younger children, with a mean age of presentation of 3 years.¹⁸⁴ There is no sexual predilection.^{86, 184, 209} These lesions may be found at any location between the glabella and the base of the columella.¹⁸⁴ Approximately 56% present as midline cysts, and 44% present as midline sinus ostia.¹⁸⁴ Rarely, multiple sinus ostia or the simultaneous occurrence of a sinus and a cyst at the glabella and nasal bridge can be seen.²⁰⁹

The most common clinical presentation is a painless, cystic enlargement of any part of the nose, associated with one or more dimples.¹⁷⁹ Externally, midline pits, fenestra, or discrete masses are present. Associated hair may protrude from the defect (pit or fenestra).^{3, 20, 27, 30, 167, 209} Intermittent episodes of inflammation or discharge of sebaceous or inflammatory material can cause a variation in the size of the mass. Signs and symptoms of meningitis or behavioral changes related to life-threatening frontal lobe abscess can be seen when intracranial extension is present.^{179, 209}

Extension of both nasal dermoid cysts and dermal sinuses varies. These lesions can end blindly in the superficial tissues, or they may extend both intracranially and extracranially.²⁰⁹ Reported incidence of intracranial extension varies between 0 and 57%.^{155, 179} Intracranial extension of dermoids typically occurs into the epidural space in the region of the crista galli. There may be further extension, between the leaves in the falx; however, it is rare for the lesion to extend beyond the interdural space.^{37, 184}

Both CT and MRI are useful in the evaluation of these lesions. The course of a dermal sinus is seen on CT as a well-defined gap between the nasal bones, in the midline or in the frontal bone.¹⁷⁹ The findings of an enlarged foramen cecum and bifid or distorted crista galli are suggestive of, but not pathognomonic of, intracranial extension (Fig. 21-9). These findings can be present with or without intracranial extension or with intracranial extension of a fibrous cord without dermoid elements.¹⁸⁴ The fibrous tract and ostium usually appear as an isodense or hypodense to soft tissue channel with variable extension. Bony canals are well seen on CT and can extend through the nasal bones, nasal septum, and skull base. Noninfected dermoid cysts appear on CT as nonenhancing masses of fat attenuation with an isodense rim to soft tissue. Stranding of the surrounding soft tissues and change in the attenuation value of the cyst suggests secondary infection of the mass. The appearance of an infected dermoid cyst is similar to an abscess with a peripheral rim of enhancement.¹¹³

MRI is extremely valuable in assessing these lesions. Thin-slice (3-mm), sagittal, coronal, and axial T1-weighted sequences should be obtained. Enlargement of the foramen cecum with intracranial extension is best demonstrated on sagittal T1-weighted images. Dermoid cysts most commonly have isointense to hyperintense T1-weighted signal as compared with brain, with associated chemical shift

Figure 21-8. Nasopharyngeal teratoma. A, Axial noncontrast CT scan. A heterogeneous mass is filling and causing marked expansion of the nasal cavity in an infant. B, Axial T2-weighted MRI scan. A mass of the posterior nasal cavity (arrowheads) extends into the left maxillary sinus in another patient. The mass shows slightly heterogeneous signal, whereas maxillary sinus disease shows hyperintense signal (curved arrow). C, Coronal T1-weighted postcontrast MRI scan. Moderate enhancement of the mass is seen after contrast administration, with the obstructive maxillary sinus disease showing a greater degree of enhancement (arrow).

Figure 21-9. Nasal dermoid. *A*, Sagittal T1-weighted MRI scan. A mass of relative isointensity to gray matter is present in the anterior nasal cavity (arrowheads). It extends through an enlarged foramen cecum (open arrow) to the intracranial cavity. *B*, Axial T1-weighted MRI scan shows a bifid appearing crista galli (arrowheads), with the intracranial portion of the nasal dermoid appearing isointense to gray matter in the area of the foramen cecum (open arrow).

artifact. Fibrous tracts are isointense to gray matter on T1-weighted sequences.

The surgical approach with these lesions is dissection of the extracranial portion of the tract to the area of the foramen cecum. If dermal elements are found in the cephalic most portion of the specimen, intracranial dissection is performed.^{184, 209}

Nasal Glioma

Nasal gliomas are congenital masses of heterotopic glial tissue with extranasal (60%), intranasal (30%), and mixed (10%) forms. These masses occur sporadically with no familial tendency or sexual predilection. They are rarely associated with other congenital malformations.²³⁴ Extranasal gliomas lie external to the nasal bones and nasal cavity and most commonly occur slightly off midline at the bridge of the nose. The intranasal form is found within the nasal or nasopharyngeal cavity, the oral cavity, or, rarely, the pterygopalatine fossa. A communication between with the extranasal and intranasal components of the mixed form occurs via a defect in the nasal bones or around lateral edges of the nasal bones.²³⁴

Extranasal gliomas clinically present as a firm, reddish to bluish, skin-covered mass that is found in early infancy or childhood. These masses do not exhibit pulsations or increase in size with a Valsalva maneuver or compression of the ipsilateral jugular vein (Furstenburg sign).²³³ They are typically slow-growing; however, they may grow more or less rapidly than the adjacent soft tissue.²³⁴ Intranasal gliomas present as large, firm submucosal masses that extend inferiorly, toward or near the nostril.²³⁴ They may cause obstruction of the nasal passage and respiratory compromise in infants or obstruction of the nasolacrimal duct

with resultant epiphora. Cerebrospinal rhinorrhea, meningitis, or epistaxis can also be seen at initial clinical presentation.

On pathologic examination, nasal gliomas resemble reactive gliosis rather than a neoplasm.¹⁴⁶ Metastasis or invasion of surrounding tissue has not been reported.²³¹ Tiny bits of fibrous or gemistocytic astrocytes, without evidence of mitotic activity, are evident on histologic examination. Fibrous septations and prominent zones of granulation tissue are also found.²³¹

Distinguishing a nasal glioma from an encephalocele is difficult on imaging unless a communication between the mass and the intracranial subarachnoid space is documented. If a communication is present, the mass is classified as an encephalocele rather than a nasal glioma. Evaluation is best accomplished with MRI in the sagittal plane. Otherwise, encephaloceles and nasal gliomas appear as masses of soft tissue signal, isointense to gray matter, without a clear distinction between the two on imaging (Fig. 21-10).

Anterior Basal Encephalocele

The reported incidence of encephalocele varies geographically. The incidence of occipital encephaloceles is greater in the United States and Western Europe, whereas anterior basal cephaloceles are more common in the Far East and parts of Asia.¹⁹² Overall, cephaloceles account for 10% to 20% of all craniospinal malformations. Anterior basal cephaloceles make up approximately 10% of cephaloceles, with the occipital form accounting for 75% and the nasal and orbital forms 15%.¹³³ The incidence of basal cephaloceles is between 1 and every 35,000 to 40,000 live births.²⁶²

Figure 21-10. Nasal glioma. A, Axial noncontrast CT scan. The anterior nasal cavity on the left is filled with a mass of slightly less than soft tissue attenuation. There is bony remodeling of the nasal bone on the left. B, Sagittal T1-weighted MRI scan. The anterior nasal mass is isointense to gray matter (arrowheads) and shows no evidence of intracranial communication.

The term *cephalocele* refers to an extracranial herniation of intracranial contents through a midline defect in the skull base and dura mater. Anomalies that contain neural elements are termed *encephaloceles*; those that contain meninges and subarachnoid space are termed *meningoceles*.¹³³

There is no universal agreement on the etiology of anterior cephalocele; however, the anomaly is thought to be secondary to imperfect closure of the anterior neuropore of the neural tube at approximately the 25th day of gestation. Cephaloceles related to the sphenoid bone may be secondary to persistence of the craniopharyngeal canal or failure of normal union of basilar ossification centers.¹⁸⁹

On histologic examination, the herniated neural tissue in an encephalocele contains neurons with prominent astrogliosis. The cyst wall is composed of glia and fibrous connective tissue without neurons.¹⁹² Basal cephaloceles are categorized according to location into the following:

- Sphenopharyngeal (through the sphenoid body and into the pharynx)
- Spheno-orbital (through the superior orbital fissure)
- Sphenoethmoidal (through sphenoid and ethmoid bones resulting in a posterior nasal mass)
- Trans(fronto)ethmoidal (through the cribriform plate resulting in an anterior nasal mass);
- Sphenomaxillary (a theoretical type that extends into the maxillary sinus)

A transsphenoidal cephalocele is a subtype of the sphenopharyngeal form, in which the herniated contents extend into the sphenoid sinus.¹⁸⁹

The most common type of basal cephalocele, the sphenopharyngeal, usually presents as a pharyngeal mass with signs and symptoms related to airway obstruction (snoring, mouth breathing, nasal obstruction) or cerebrospinal fluid leak (runny nose).^{170,262}

Frontoethmoidal encephaloceles commonly present in the neonatal or infantile period with a nasal mass or nasal stuffiness; nasopharyngeal cephaloceles present toward the end of the first decade with mouth breathing or nasal stuffiness. Craniofacial anomalies are not uncommon with frontoethmoidal cephaloceles. Pituitary and hypothalamic dysfunction and a decrease in visual acuity can be seen with sphenoethmoidal and sphenopharyngeal cephaloceles secondary to herniation of the pituitary gland, hypothalamus, and optic apparatus into the sac. Agenesis of the corpus callosum is found in approximately 80% of these patients.¹⁶

Coronal CT of the skull base is useful in evaluating the typically smooth and well-defined bony margins of the defect as well as the soft tissue component of the lesion. CT with intrathecal contrast material may be useful in determining the continuity of the subarachnoid space with this anomaly; however, this is rarely needed with the availability of MRI evaluation. MRI is superior in evaluating the contents of the cephalocele to include (1) the exact position of the pituitary stalk and gland; (2) the position and state of the optic nerves, chiasm, and optic tracts; (3) the state of the limbic system and cingulate gyrus; (4) the degree of bony dehiscence of the skull base; and (5) the presence of other anomalies¹⁹⁰ (Fig. 21-11).

Figure 21-11. Trans(fronto)ethmoidal encephalocele. *A*, Coronal T1-weighted MR image shows inferior displacement of the right gyrus rectus, with continuity of neural tissue extending through the foramen cecum (arrowhead) and into the right anterior nasal cavity (curved arrow). The mass contains a small amount of neural tissue (arrowhead) in addition to cerebrospinal fluid. *B*, Sagittal intermediate-weighted image demonstrates extension of the neural tissue through the foramen cecum (arrows).

Malignant Neoplasms

Primary malignancies of the head and neck comprise approximately 5% of all malignant neoplasms in the pediatric age group.¹¹¹ Lymphoma and rhabdomyosarcoma are the most common tumors in this category; however, primary neuroblastoma, nasopharyngeal carcinoma, thyroid carcinoma, and synovial sarcoma also occur in children.¹¹¹

Lymphoma

Malignant lymphoma represents a heterogeneous group of solid lymphoreticular neoplasms.^{139, 217} It is the second most common solid malignant tumor in children and the most common malignancy in the head and neck in this age group.¹¹¹ This tumor accounts for approximately 50% of pediatric head and neck malignancies and is equally divided between non-Hodgkin's lymphoma and Hodgkin's lymphoma.^{98, 111}

Hodgkin's Disease

Hodgkin's disease has a bimodal age distribution, with the first peak occurring in teenagers and young adults (with a fairly good prognosis) and the second peak in adults over 40 years of age (with a less optimistic prognosis). The disease is rarely encountered in children younger than 5 years of age. There is a male predominance of 3:1 in

the preteen years, with the female incidence increasing with age.¹⁴⁶

Most patients present with painless adenopathy, with 80% to 90% involving cervical lymph nodes. Fever, night sweats, and weight loss are seen as associated systemic symptoms.²⁴⁸

Histologically, the tumor consists of polymorphous infiltration of malignant cells (Reed-Sternberg and their mononuclear variants) with morphologically normal reactive cells (lymphocytes, plasma cells, and eosinophils). The diagnostic Reed-Sternberg cell contains multiple nuclei with eosinophilic nucleolus and moderately abundant, slightly eosinophilic cytoplasm. The Rye histologic classification is based on the proportion of lymphocytes and histiocytes in the lymph nodes.^{40, 120, 145} Hodgkin's disease has been subclassified into the following forms: (1) lymphocyte predominance, (2) nodular sclerosing (rare in children), (3) mixed cellularity, and (4) lymphocyte depletion.¹⁴⁵

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma tends to occur in children between the ages of 7 and 11 years, with a male predominance of 3:1. Approximately 15% of cases arise in the head and neck. This disease may involve virtually any structure in the head and neck; however, the majority of children with this form of lymphoma have widespread disease with bone marrow involvement at diagnosis.⁹²

The clinical presentation is a neck mass or masses that can cause pressure on vital structures, leading to symptoms related to tracheal compression or superior vena cava syndrome. Primary involvement of Waldeyer's ring may lead to middle ear effusion or nasal obstruction, whereas Burkitt's lymphoma can present as a large mass of the jaw, thyroid, or parotid gland.

The most common histologic types of non-Hodgkin's lymphoma are^{36, 53, 126}:

- Malignant lymphoma, lymphoblastic (30% to 35%)
- Malignant lymphoma, undifferentiated (Burkitt's and non-Burkitt's) (40% to 50%)
- Large-cell (15% to 20%)

Histologically, cytologically, and immunologically, the tumor cells in lymphoma and acute lymphoblastic leukemia share some common properties. These two disease processes are better conceptualized as a spectrum of disease rather than separate processes. Leukemia is associated with primary bone marrow involvement; non-Hodgkin's lymphoma, primary lymph node involvement. Arbitrarily, if greater than 25% of bone marrow cells are lymphoblasts, the diagnosis is leukemia.

Imaging is usually not helpful in differentiating Hodgkin's from non-Hodgkin's disease or metastatic lymphadenopathy. The sites of tumor deposition are subdivided as follows⁹⁴:

- Nodal (most common)
- Extranodal, lymphatic (Waldeyer's ring)
- Extranodal, extralymphatic (orbit, paranasal sinuses deep fascial spaces, mandible, salivary glands, skin, and larynx)

Hodgkin's disease shows more predictable biologic behavior. The disease typically spreads from one nodal group to the next contiguous nodal group. Extranodal disease is rare in Hodgkin's disease.^{40, 94, 139} In contrast, extranodal disease, with or without associated nodal involvement, occurs frequently in non-Hodgkin's disease. Waldeyer's ring, paranasal sinuses, and nasal cavity are the most common extranodal sites of disease in non-Hodgkin's lymphoma.¹³⁹ Widespread disease at presentation is also more common in patients with non-Hodgkin's lymphoma, with cervical adenopathy only part of the clinical picture rather than the major finding.^{40, 94, 139} However, both Hodgkin's and non-Hodgkin's lymphomas can present as painless neck masses with unilateral or bilateral cervical adenopathy, involving the mid and lower jugular nodal chains, with relative sparing of the upper jugular chains.^{94, 139}

CT demonstrates nodal and extranodal masses of intermediate attenuation (Fig. 21-12); MRI shows homogeneous, intermediate-signal-intensity masses on all pulse sequences.⁹² Mild peripheral enhancement can be seen after administration of contrast medium. Calcification of lymph nodes is rare in untreated lymphoma and necrosis of lymph nodes is uncommon.⁹⁴ Sonography of cervical adenopathy in patients with lymphoma demonstrates multiple areas of decreased echogenicity, simulating cystic masses. When lymphoma involves the nasopharynx, it usually displays less aggressive imaging characteristics and lacks bone destruction; however, this is not a constant finding. When bony destruction is present, it is typically a permeative

pattern rather than the aggressive, lytic pattern found in rhabdomyosarcoma and squamous cell carcinoma.^{92, 139}

In addition to imaging the neck, evaluation of patients with head and neck lymphoma should include CT of the chest and abdomen. Gallium 67 scanning is also recommended in the initial staging of the tumor, evaluation of response to treatment, and detection of recurrent and metastatic disease as well as a predictor of clinical outcome in both Hodgkin's and non-Hodgkin's disease.⁷⁵

Infectious causes, such as infectious mononucleosis syndrome and human immunodeficiency virus, as well as phenytoin (Dilantin) hypersensitivity, rheumatoid arthritis, and systemic lupus erythematosus, can produce a pattern of adenopathy similar to lymphoma on imaging.⁶²

Rhabdomyosarcoma

Soft tissue sarcomas account for 7% of all malignancies in children younger than 15 years of age in the United States. More than 50% of these tumors are rhabdomyosarcomas, with approximately 38% found in the head and neck.¹⁵⁰ Rhabdomyosarcoma is a malignant tumor that arises from primitive pluripotential mesenchymal cells that are capable of differentiating into skeletal muscle. Thus, these tumors may develop anywhere in the body.¹³⁷

The most common site of primary head and neck rhabdomyosarcoma in children is the orbit and nasopharynx, followed by the paranasal sinuses and middle ear. Other locations in the head and neck include the parapharyngeal soft tissues and nasal cavity.^{41, 137, 207} There is a bimodal age distribution occurring at 2 to 5 years of age and in the late teenage years. Most patients are younger than 10 years of age at presentation.^{150, 151}

The clinical presentation varies with the anatomic site of the tumor. Those tumors found in the neck present as a painless, enlarging mass. Parameningeal rhabdomyosarcomas usually present with a bloody discharge from the nose or ear, chronic otitis media with or without a facial nerve palsy, or symptoms attributed to an upper respiratory infection. Orbital rhabdomyosarcomas typically present with rapid development of proptosis, decreased vision secondary to optic nerve compression, or a palpable mass leading to an early diagnosis.^{137, 207}

Histologically, there are four distinct subtypes of rhabdomyosarcoma:

- Embryonal
- Botryoid (a variant of embryonal)
- Pleomorphic
- Alveolar

The embryonal form is the most common subtype found in the head and neck in children. These densely cellular tumors are composed of lymphocyte-sized cells with hyperchromatic, round to oval nuclei and stellate or bipolar cell processes. Rhabdomyosarcomas tend to have a loose stromal network with a high overall water content. The pleomorphic type is seen only in adults, and the alveolar type occurs the extremities of older children and young adults.^{41, 264}

The Intergroup Rhabdomyosarcoma Study divided head and neck rhabdomyosarcomas into three categories based

Figure 21-12. Lymphoma. *A*, Hodgkin's disease. Axial post-contrast CT scan. A large nodal mass (arrowheads) is present in the left neck with involvement of multiple spaces (retropharyngeal, mucosal, parapharyngeal, carotid, and posterior triangle). Mild enhancement of the mass and encasement of the internal carotid artery (open arrow) are present. The internal jugular vein is compressed and not visualized. *B* and *C*, Non-Hodgkin's disease. *B*, Coronal fast spin-echo (FSE) MRI scan. A rounded, intermediate signal mass is protruding into the nasopharynx from the pharyngeal tonsils. *C*, There is mild peripheral enhancement (arrowhead) after administration of contrast medium on this coronal T1-weighted image.

on site of origin: (1) orbit, (2) parameningeal (middle ear, paranasal sinuses, nasopharynx), and (3) all other head and neck sites. Those tumors that are paramedian in location (nasopharynx, paranasal sinuses, nasal cavity) have a tendency to extend through the skull base and to invade the meninges. Bony erosion has been reported in 18% of the tumors in this subgroup and 67% of middle ear tumors.^{41, 264} The tumor spreads to the lymph nodes of the neck in 12% to 50% of cases. Hematogenous spread also occurs to lung, bone, brain, bone marrow, and breast.^{41, 257, 264}

The usual CT appearance of rhabdomyosarcoma is a poorly-defined, inhomogeneous mass that distorts soft tissue planes and causes bony destruction. After contrast administration, rhabdomyosarcomas usually enhance to the same degree as adjacent muscle on CT.^{41, 137} Although MRI findings are not specific, most rhabdomyosarcomas are isointense to minimally hyperintense to muscle on T1-weighted sequences and hyperintense to muscle and fat on T2-weighted sequences. The signal intensity can be homogeneous (most common) or heterogeneous, and there

is marked enhancement after contrast administration (Fig. 21-13). Intratumoral hemorrhage can be present.²⁶⁴

Because meningeal involvement is the worst prognostic indicator in head and neck rhabdomyosarcoma, sagittal and coronal postcontrast MRI with fat saturation is crucial in evaluating potential dural and meningeal disease and intracranial extension.²⁵ Coronal CT is the imaging modality of choice for evaluation of bone destruction of the skull base.⁴¹ Thus, all patients with suspected rhabdomyosarcoma should undergo both CT and MRI.

The MRI characteristics of this tumor are similar to those of lymphoma and nasopharyngeal carcinoma. AIDS-related Kaposi's sarcoma may also have similar imaging characteristics; however, generalized adenopathy in the neck is typically present with rhabdomyosarcoma.²⁶⁵

Those tumors that are not amenable to a good surgical outcome (middle ear, nasopharynx, paranasal sinuses) are treated with chemotherapy and irradiation. If intracranial extension is detected, additional radiotherapy is given to the base of the brain with whole brain irradiation as well

Figure 21-13. Rhabdomyosarcoma. Sagittal (A) and axial (B) postcontrast T1-weighted MRI scans. There is marked enhancement of the mass filling the nasal cavity and nasopharynx. Extension can be seen intracranially along the floor of the anterior cranial fossa (A) (arrows) and the medial aspect of the middle cranial fossa (B) (arrowheads) as well as into the left orbit (B) (arrows). C, Coronal T1-weighted MRI scan in a second patient demonstrates intracranial extension of an enhancing infratemporal fossa mass through the foramen ovale on the right (arrows).

as intrathecal chemotherapy. With the remainder of the tumors, it is assumed that all patients have systemic disease at presentation; consequently, they are treated locally and regionally with surgery and irradiation, or both, as well as systemically with chemotherapy.¹⁵²

The prognosis is closely related to initial extent of disease.²³⁸ The tumors with associated parameningeal disease commonly present with advanced disease (grade III

or IV) and carry a 35% to 64% 2-year disease-free survival rate. This poor survival rate is secondary to the tendency for invasion of the skull base with associated meningeal and intracranial disease. Orbital rhabdomyosarcoma carries the best prognosis, with an 80% to 90% 2-year disease-free survival rate. All other head and neck primary tumors carry an intermediate prognosis, approximately a 78% 2-year disease-free survival rate.^{79,137}

Neuroblastoma

Neuroblastoma is a neural crest tumor arising from the sympathetic nervous system. Overall, it represents the most common malignant tumor in children younger than 1 year of age, with the most frequent primary sites the adrenal gland and retroperitoneum.¹²⁹ The occurrence of this tumor in infants in a primary cervical location is rare, accounting for less than 5% of all neuroblastomas. Most neuroblastomas located in the neck represent metastatic disease from an abdominal or thoracic primary tumor.^{39,224}

Patients present with a painless, smooth, rubbery mass with symptoms of dysphasia, hoarseness, stridor, and respiratory difficulty.^{2,224} Horner's syndrome, with accompanying hematochromia of the iris, has also been reported.²

Histologic examination reveals a densely cellular tumor composed of small cells, sometimes arranged in whirls or rosette-like structures with intermingled larger primitive ganglion-like cells and intercellular neuronal tissue. A spectrum of maturational changes is seen from the most immature, malignant neuroblastoma to benign ganglioneuroma. Bone marrow involvement is common.²¹⁶

Because patients are young infants presenting with a neck mass, ultrasound is often the initial imaging modality. Sonographic findings are nonspecific, showing a hypoechoic or complex mass with evidence of cervical adenopathy. Small echogenic foci, consistent with calcifications, are sometimes present.² CT scans reveal a sharply circumscribed mass in the poststyloid parapharyngeal space. Calcifications may be present on noncontrast images. Because the mass usually originates posterior to the vascular sheath, the carotid artery and jugular vein are displaced anteriorly.

After contrast administration, the tumor enhances to the same degree or slightly greater than muscle (Fig. 21-14).

Increased signal intensity to muscle is seen on T1-weighted and T2-weighted MRI. MRI is superior to CT in the evaluation of these tumors. MRI better delineates the mass and demonstrates the interfaces between the mass and surrounding soft tissue structures as well as the exact relationship of the tumor to the surrounding vessels.^{61,72}

With cervical neuroblastoma, intracranial extension is rare, and only one case of intraspinal extension has been reported in this location.^{54,188} Because cervical neuroblastoma is more commonly a metastatic lesion, chest and abdominal CT, as well as nuclear MIBG whole body imaging, should be performed in the initial evaluation to rule out other sites of involvement.

Differential considerations are limited to those processes that involve the poststyloid parapharyngeal and carotid spaces, including nodal tumors (metastases, lymphoma) and neurogenic tumors (schwannoma, neurofibroma, paraganglioma).

Treatment is based on stage of the disease, age of the patient at diagnosis, and other biologically determined factors.²⁹ The treatment is complex and may include surgery, radiotherapy, chemotherapy, and bone marrow transplant. Cervical neuroblastoma is frequently localized, at stage I or II. Infants younger than 1 year of age have the best overall survival rate (74% to 82%) with neuroblastoma. This possibly reflects both early presentation as well as spontaneous regression and maturation of the tumor to a benign ganglioneuroma in young infants. Papillary carcinoma of the thyroid has been reported in these patients years after radiotherapy treatment.⁵⁴

Figure 21-14. Cervical neuroblastoma. Axial precontrast (A) and postcontrast (B) CT scans. A, Small areas of calcification are seen (arrowhead) in a large mass of slightly decreased attenuation in the posterior triangle. B, There is moderate, homogeneous enhancement after contrast administration.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is rare in children, accounting for fewer than 1% of pediatric malignancies.^{4, 18, 43} An increased incidence of this tumor has been noted in certain geographic locations and populations, specifically in southern China and Alaska. In Taiwan, nasopharyngeal carcinoma represents the most common cancer among Chinese males.¹⁰⁶ There also appears to be an increased incidence in the African American population in the United States.^{63, 263}

The most common clinical presentation of childhood nasopharyngeal carcinoma is tender cervical adenopathy. This reflects the regional spread of the tumor at initial presentation. Serous otitis media can be seen from eustachian tube obstruction by the tumor or interference of muscular action of the tensor veli palatini muscle. Nasal obstruction; epistaxis; referred pain to the ear, neck, or throat; or cranial nerve paresis can be noted at presentation. Distant metastases are uncommon at initial diagnosis.^{213, 237}

Nasopharyngeal carcinoma is an undifferentiated epidermoid-type tumor rather than an adenocarcinoma or a sarcoma. Multiple cell patterns (e.g., squamous cell, transitional cell, spindle cell, clear cell, polyhedral cell) can be seen with these tumors. On the basis of these cell types, a simplified approach to the classification of these tumors has been adopted by the World Health Organization, in which three types are proposed²¹⁴:

- Type I, keratinizing squamous cell carcinoma
- Type II, nonkeratinizing squamous cell carcinoma
- Type III, undifferentiated carcinoma

Types I and II have been associated with Epstein-Barr virus, whereas type III has been associated with childhood nasopharyngeal carcinoma. In the pediatric age group, nasopharyngeal carcinoma is usually an undifferentiated, epidermoid carcinoma or lymphoepithelioma (transitional cell).^{70, 112, 144}

MRI or CT should be used to evaluate the nasopharyngeal area and skull base. Nasopharyngeal carcinoma usually arises in the posterior lateral wall of the nasopharynx in the region of the fossa of Rosenmueller. It may obstruct the lateral recess and cause asymmetry of the airway secondary to mass effect. The tumor can also originate from the posterior-superior wall, the posterior wall, or the anterior wall of the nasopharynx.²¹

CT is ideal for evaluation of bony erosion of the skull base, which is not uncommon with nasopharyngeal carcinoma.²²⁰ However, MRI has been found superior to CT in the evaluation of primary lesions of the nasopharynx in both adults and children.²⁶¹ Undifferentiated carcinomas are invasive tumors with poorly defined margins and associated bony destruction. On CT scans, these tumors tend to be noncalcified with a variable enhancement pattern (Fig. 21-15). The magnetic resonance (MR) signal intensity of the masses is isointense to muscle on T1-weighted images and isointense to hyperintense to muscle on T2-weighted images.¹⁸⁵ Homogeneous, hypointense T1-weighted signal intensity and inhomogeneous, hyperintense T2-weighted signal intensity with inhomogeneous enhancement after contrast administration has been reported with squamous cell carcinoma of the oral cavity. Necrotic cervical adenopathy is common, particularly in the retropharyngeal and high jugular chains.²⁶¹

Figure 21-15. Nasopharyngeal carcinoma. Coronal noncontrast CT scan. A soft tissue mass is present in the roof of the oral cavity, causing erosion of the hard palate and maxilla (arrowheads).

In children, differential considerations by imaging primarily include lymphoma, rhabdomyosarcoma, neuroblastoma, and, occasionally, juvenile nasopharyngeal angiofibroma or inflammatory processes that destroy bone.⁹⁷ The most common sites of metastatic disease are the cervical lymph nodes, lungs, and bone; as a result, survey CT of the chest and nuclear bone scanning should be included in the imaging workup of these tumors.²²⁰

Treatment is focused on local control of disease with radiotherapy, with or without chemotherapy, before metastatic spread occurs.¹¹² The 5-year relapse-free survival rate is 36%, with an overall 5-year survival rate of 51%.¹¹¹

Thyroid Carcinoma

Thyroid carcinoma is uncommon in the pediatric age group, representing 1% to 1.5% of all malignancies in children. This neoplasm primarily occurs in older children and adolescents, particularly females. In contrast to thyroid carcinoma in adults, the tumor in children tends to be more aggressive at diagnosis; however, the prognosis is generally good.^{23, 73, 78, 250, 267}

In the past, the relationship between radiotherapy and thyroid carcinoma was well known, with 20% to 50% of children with this neoplasm having a history of radiation exposure.^{208, 268} The use of radiotherapy for benign conditions such as thymic enlargement, tonsillar and adenoidal hypertrophy, hemangioma, and lymphatic malformation peaked in the 1940s, with a resultant increase in thyroid carcinoma in the 1960s and 1970s.^{69, 251} Although the use

of radiotherapy for such benign conditions in children has declined, a greater number of children are surviving cancer with adjuvant radiotherapy. Thus, delayed thyroid carcinoma may become more of a concern in the future. The period between exposure to radiation and the occurrence of thyroid carcinoma may be as long as 25 years.²⁶⁸

The differentiated carcinomas (papillary and follicular) most commonly present with cervical lymphadenopathy or a thyroid nodule. There is a high incidence of cervical metastases (43 to 87%) and pulmonary metastases (up to 15%) at presentation in children with this type of thyroid carcinoma.^{78, 202, 250} The clinical course in these children appears to be similar to sporadic thyroid carcinoma.^{69, 251}

Thyroid carcinoma is subdivided into the following types:

- Differentiated (papillary or follicular)
- Medullary
- Anaplastic or nondifferentiated

The *papillary* form is the most common type found in children, accounting for approximately 90% of cases.^{73, 96, 259} This tumor is well differentiated, with cuboidal epithelium on fibrovascular stalks projecting into cystic spaces. Squamous metaplasia, psammoma bodies, oxyphilic change, and lymphatic invasion are common.¹⁵⁶ Pure *follicular* adenocarcinoma is the second most common type of thyroid carcinoma occurring in children, accounting for 5% to 10% of cases.^{73, 96}

Medullary carcinoma accounts for approximately 5% of thyroid neoplasms in children. These tumors originate from parafollicular cells (C cells), which are derived from neural crest tissue that migrate to the thyroid during embryogenesis.

Anaplastic carcinoma rarely occurs in children.¹²³

Microscopically, these tumors have a variable pattern of solid and follicular growth with malignant change, demonstrated by evidence of angioinvasion or invasion of the capsule. Pulmonary and osseous metastases and blood vessel invasion are more common with follicular adenocarcinoma than with papillary carcinoma.^{6, 259}

On radionuclide scanning, thyroid carcinoma is usually "cold" (nonfunctioning) but rarely may be "hot" (functioning).⁷⁸ After a mass has been localized to the thyroid gland by radionuclide scanning or palpation, sonography can determine whether the mass is cystic or solid. Cystic masses in the thyroid gland are almost always benign, representing an adenoma or colloid cyst; however, they may be complicated by hemorrhage and/or debris, simulating a solid or mixed tumor. Occasionally, malignant thyroid lesions are purely cystic.^{11, 78} Most thyroid carcinomas have ill-defined margins and variable echogenicity, as compared with the normal thyroid gland.^{78, 205, 221} Microcalcifications, irregular margins, and detectable flow in the mass by Doppler imaging raises the suspicion of malignancy.

Ultrasound is also useful in detecting nonpalpable metastatic lymph nodes. Echogenic foci within the mass or lymph nodes, representing calcifications, are characteristic of primary or metastatic medullary carcinoma.^{78, 85} In the presence of a known thyroid carcinoma, a survey CT of the neck should be performed to evaluate for metastatic lymphadenopathy (Fig. 21-16).^{76, 85, 227}

MRI has been reported to be helpful in differentiating

Figure 21-16. Thyroid carcinoma. Axial postcontrast CT scan. A subtle area of relatively decreased attenuation is noted in the posterior aspect of the right lobe of the thyroid gland.

recurrent thyroid carcinoma from fibrosis. On MRI, recurrent carcinoma appears as low to medium T1 signal intensity and medium to high T2 signal intensity, whereas low signal intensity on both T1-weighted and T2-weighted sequences is noted with fibrosis. In this setting, "low" signal is defined as less than muscle; "medium" signal, greater than muscle but less than fat; and "high" signal, greater than or equal to fat.¹⁰ Thyroid masses with partial destruction of the pseudocapsule on MRI may suggest papillary carcinoma.¹⁷⁶

Surgery is the mainstay of treatment for primary thyroid carcinoma.^{134, 267} The best survival rates are with papillary carcinoma (86.3%) followed by follicular (85.3%), medullary (44%), and anaplastic (19%) types.^{73, 96, 202} The overall mortality rate for children with thyroid carcinoma is 17%, with 75% of patients dying of complications of the tumor rather than the disease.^{23, 73, 78, 250, 259, 267}

Synovial Sarcoma

Synovial sarcoma accounts for approximately 8% to 10% of all soft tissue malignancies, with 85% occurring in the extremities.^{166, 218} Despite the name, these neoplasms do not arise from synovial tissue but are so named because of their similarity to synovium.²¹⁹ Synovial sarcomas usually arise in or near tendon or tendon sheaths rather than joints or bursal surfaces. Synovial tissue is not usually found in head and neck; synovial sarcomas are thought to arise from pleuripotential mesenchymal tissue that can differentiate into synovial cells.^{22, 91, 131} The most common sites of synovial sarcoma in the head and neck are the cervical soft tissues and parapharyngeal tissues, with an orofacial location less common.^{199, 218}

Patients typically present between 15 and 35 years of age, with a slight male predominance.¹⁶⁵ The most common clinical presentation is a painless mass with symptoms of dysphagia, hoarseness, and headache.⁷

Histologically, synovial sarcomas may be *biphasic* and

monophasic. The biphasic type contains epithelial and spindle cell components; the monophasic type contains only spindle cells.¹⁰⁰ These well-circumscribed tumors contain gland-like spaces or clefts, surrounded by fibrosarcoma-like areas.⁶⁶

CT is useful in demonstrating calcification and evaluating erosive changes of bone associated with synovial sarcomas. Calcification, in the form of round concretions, is present in approximately 30% of soft tissue sarcomas and may be a helpful finding in distinguishing this mass from other head and neck primary tumors in **children**.¹⁹⁵ MRI, however, is considered the imaging modality of choice for detection and staging of this tumor because of its inherent better soft tissue resolution. Tumor extent, vascular invasion, and intratumoral hemorrhage are better assessed by MRI.²¹⁹ Synovial sarcomas of the head and neck have variable, heterogeneous MRI signal on both T1-weighted and T2-weighted sequences, with variable heterogeneous enhancement after contrast administration.²¹⁹

In our experience, we have found the imaging appearance to most commonly be a well-defined mass with an irregular wall, necrotic center, and minimal wall enhancement on CT; however, this tumor may be solid, cystic, or mixed in composition^{195,219} (Fig. 21-17). Because 12.5% of patients have metastases to cervical lymph nodes at presentation, CT or MRI of the neck should be included in the initial evaluation. CT of the chest should also be performed, since pulmonary metastases are not uncommon.^{9,199}

Treatment is surgical with wide local excision. Radiation and chemotherapy may be used as adjunctive treatment if excision is not complete.¹⁶³ The rate of local recurrence

is high, with metastases to the lungs usually occurring within 2 years.⁹¹ The survival rate is 40% at 5 years and 25% at 10 years, primarily because of pulmonary metastases.^{91,163,199,218}

Benign Masses

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) comprises 0.5% of head and neck tumors in children.⁵⁶ This benign but locally invasive tumor of the nasopharynx is the most commonly encountered vascular mass of the nasal cavity in children.²² The name of the tumor arises from the fact that it is almost exclusively found in adolescent males.⁵⁶ Patients with JNA usually present between 7 and 21 years of age, with a peak incidence between 14 and 18 years.²² Although the etiologic mechanism of this tumor has not been defined, it arises from the fibrovascular stroma normally found in the nasopharynx. Most JNAs arise in the area of the sphenopalatine foramen and pterygopalatine fossa.²²

Patients most commonly present with complaints of nasal obstruction (91%) or severe, spontaneous epistaxis (59%). Other signs and symptoms include purulent nasal rhinorrhea from associated sinus infection, hyponasal speech, anosmia, facial deformity secondary to the locally invasive nature of the tumor, exophthalmos, hearing loss, or rarely signs of intracranial mass effect from extension of the tumor. Episodes of recurrent epistaxis have been related to the vascular fragility of the tumor, which is thought to be secondary to increased levels of circulating estrogens.^{22,136}

Histologically, JNAs are composed of spindle or stellate fibrocytes in a connective tissue stroma with many wide, thin-walled vessels. The myofibroblast represents the principal cell of the tumor. Myofibroblasts interfere with the synthesis of collagen and elastin and are capable of transforming into smooth muscle.¹³⁶ Fine vessels invade the fibrovascular stroma, producing pseudolymphatic endothelialized spaces. The final appearance of the tumor represents a spectrum from a cellular or purely fibrous mass, to a cavern-like mass with a fibrovascular stroma. If the fibrous component of the tumor predominates, the incidence of local invasion and the frequency of epistaxis are decreased.⁵⁶

Imaging gives important information for both the diagnosis and management of these tumors. JNAs are slow-growing masses that extend along and through fissures and foramina. They usually remodel bone rather than destroy it.¹⁰² JNAs can extend in multiple planes, including medially into the nasopharynx, laterally through the pterygopalatine fossa and pterygomaxillary fissure and into the infratemporal fossa, and superiorly via foramina at the skull base or the sphenoid sinus into the middle cranial fossa and cavernous sinus. They tend to slowly enlarge over time and may involve the paranasal sinuses (ethmoid, maxillary, and sphenoid), and orbits.²¹⁰

Anterior bowing of the posterior wall of the maxillary sinus on plain film (Holman-Miller sign) was the earliest reported radiographic finding with JNA,¹⁰² although this finding is not specific.²³⁵ This tumor should be evaluated

Figure 21-17. Synovial sarcoma. Axial postcontrast CT scan demonstrates a large, well-defined parapharyngeal mass with extension into the hypopharynx. The mass has an irregular wall, a necrotic center, and no evidence of significant enhancement.

with CT, MRI, and angiography. CT is useful for the evaluation of bony involvement, whereas MRI is better for determining intracranial extension of tumor and differentiating tumor extension into sinuses from postobstructive sinus disease. CT and MRI should be performed without and with contrast in axial and coronal planes. Fat saturation should be employed with postcontrast MR images.

Findings can include a nasopharyngeal mass, widening of the pterygopalatine fossa, anterior displacement of the posterior maxillary sinus wall with associated widening of the pterygomaxillary fissure, opacification of one or more paranasal sinuses, erosion of the sphenoid bone with a mass in the sphenoid sinus, erosion of the hard palate or medial wall of the maxillary sinus, deviation of the nasal septum, and intracranial extension. On MRI, JNA is isointense to hypointense to muscle on T1-weighted images and isointense to hyperintense to muscle on T2-weighted images.^{80, 143} Flow voids are often present on MRI, and homogeneous, intense enhancement is typically seen on both CT and MRI scans after contrast administration (Fig. 21-18).^{56, 210, 211}

Angiography is useful to define the vascular supply of the tumor for preoperative embolization. Typically, JNAs are supplied by branches of the external carotid artery, most commonly the internal maxillary or ascending pharyngeal artery. Numerous hypertrophied and tortuous vessels are seen without segmental narrowing, beading, or aneurysm formation. A persistent, dense blush is present throughout the capillary and venous phases. Early draining veins and arteriovenous shunting are usually absent.^{135, 196} To fully define the potential vascular supply of the tumor, bilateral internal and external carotid artery injections as well as selective injections of the ipsilateral internal maxillary, ascending pharyngeal, and ascending palatine arteries should be performed.^{135, 136}

From an imaging standpoint, the primary differential consideration is an angiomatous polyp. Patients may have similar symptoms; however, angiomatous polyps tend to occur at a slightly older age (in the 3rd decade). Angiomatous polyps are located primarily in the nasal cavity and do not invade the pterygopalatine fossa or intracranial cavity. Only rarely is there extension of angiomatous polyps into the sphenoid sinus, and the mass is hypovascular or avascular on MRA with only a few feeding vessels present. The enhancement pattern is less intense than with JNA, and flow voids are not present on MRI scans.²³² Other considerations of a nasopharyngeal mass in children include lymphoma, rhabdomyosarcoma, nasopharyngeal carcinoma, and esthesioneuroblastoma.²⁰

To assist in selecting the best surgical approach, Sessions and colleagues developed a staging calcification based on extent of the lesion.²¹⁰ The most common approach to therapy is total resection (as feasible) within 24 hours of embolization. Radiotherapy is reserved for inoperative disease or residual disease, when reoperation is not practical. Intracranial extension of tumor does not always preclude surgery; however, parasellar disease may make en bloc resection impossible. In such a case, patients usually undergo debulking with extensive beam radiotherapy.^{28, 89, 121} In addition to embolization, hormonal therapy and cryotherapy are reported to be adjunctive treatments to surgery. The efficacy of testosterone agonist and estrogen

therapy (to cause involution of blood vessels) and cryotherapy (to control bleeding from small tumors) have not been widely accepted.^{8, 71}

The long-term prognosis of this benign tumor is good. Surgery alone carries a 25%–60% recurrence rate; radiotherapy alone carries a 25% recurrence rate.^{117, 136} Recurrence usually occurs within the first 12 months of therapy and is unusual after 24 months. Factors predisposing to recurrence include the multilobulated nature of the tumor, leading to invasion of adjacent sinuses and fascial planes. The natural irregularity of the nasopharynx also makes complete extirpation difficult in some cases.^{117, 136}

Neurogenic Tumors

Tumors of neurogenic origin constitute a small but significant group of head and neck masses in children.⁴⁶ Neurofibromas and schwannomas represent the most common nerve sheath tumors of the peripheral nerves in the head and neck.²¹ Solitary neurofibromas and schwannomas can be seen as sporadic lesions, whereas plexiform and multiple neurofibromas occur in association with neurofibromatosis type 1.^{20, 122} Approximately 25% of solitary neurogenic tumors originate along the course of a cervical or cranial nerve, with the exception of the olfactory nerve, which lacks schwann cells, and the optic nerve.¹⁹⁴ Twenty-five percent to 45% of schwannomas occur in the head and neck. The most common locations include the face, scalp, orbit, oral cavity, parapharyngeal space, middle ear, larynx, and neck.^{55, 83, 84, 122, 233, 236}

The normal nerve fiber is ensheathed by schwann cells (the neurolemma) which in turn, is surrounded by the endoneurial fibroblasts (the neurilemma). The schwann cell is thought of as the precursor of the neurofibroma, the schwannoma, and, probably, the neurogenic sarcoma.²⁴⁶

Neurofibromas are unencapsulated nerve sheath tumors that are composed of schwann cells, with collagen in a mucous matrix. Solitary neurofibromas are typically subcutaneous and well defined, whereas plexiform neurofibromas are more commonly infiltrative with ill-defined margins. Multiple and plexiform neurofibromas are associated with neurofibromatosis type 1. Five percent to 13% of plexiform neurofibromas undergo malignant degeneration.²⁰

Schwannomas are encapsulated tumors, usually attached to or surrounded by a nerve. Microscopically, they are composed of two types of tissues: cellular Antoni type A and less cellular Antoni type B. Compact spindle cells in parallel orientation with palisading nuclei oriented around bundles of fiber form Verocay bodies. Schwannomas are almost never associated with neurofibromatosis type 1 and rarely undergo malignant change.²⁰

Neurofibromas can arise at any age. Schwannomas most commonly present between 20 and 50 years of age, with occasional occurrences in childhood. Neurofibromas are characteristically asymptomatic, whereas schwannomas are often painful and tender. The pain may be localized or radicular in nature with associated paraesthesias.²⁰

On imaging, solitary neurofibromas and schwannomas present as well-defined lobulated masses with a tendency to cross fascial planes. Neurofibromas appear as isointense masses to muscle with rare calcification and variable en-

Figure 21-18. Juvenile nasopharyngeal angiofibroma. A, Axial T2-weighted MRI scan. The posterior nasal cavity and nasopharynx are expanded by a large mass of mixed-signal intensity (*open arrows*). B and C, Postcontrast axial (B) and coronal (C) MRI scans show flow voids within the mass (B), with extension through the sphenopalatine foramen (C) (*arrow*), the pterygopalatine fossa, and the pterygomaxillary fissure (B) (*arrowheads*) and into the infratemporal fossa (C) (*curved arrow*). D, Selective internal maxillary artery angiogram demonstrates multiple, tortuous, and hypertrophied branches supplying this nasal mass.

hancement on CT. Schwannomas typically enhance more homogeneously, with either iodinated contrast or gadolinium. On MRI, neurofibromas are hypointense to isointense to muscle on T1-weighted images and hyperintense to muscle on T2-weighted images. Variable enhancement is seen after contrast administration (Fig. 21-19). Schwannomas have intermediate T1-weighted signal and hyperintense T2-weighted signal to muscle, with more uniform enhancement after contrast administration. Heterogeneous

signal intensity can be seen centrally in these tumors secondary to cystic degeneration and hemorrhage. This event is more common with schwannomas.²³³

Plexiform neurofibromas are poorly defined, infiltrative masses that can erode bone and expand neural foramina of the cervical spine. They have a more complex appearance on MRI, with wavy cords of signal hypointensity surrounded by areas of mixed isointensity and hyperintensity on T2-weighted images.²³³

Figure 21-19. Plexiform neurofibroma. Coronal T1-weighted, postcontrast MRI scan with fat saturation. The majority of the right masticator space is involved with an ill-defined, heterogeneously enhancing mass (open arrowheads) in this patient with neurofibromatosis.

Esthesioneuroblastoma

Esthesioneuroblastoma, or olfactory neuroblastoma, is a neurogenic tumor related to the primordia of the olfactory apparatus. This uncommon neural crest tumor originates from olfactory epithelium of the superior nasal cavity or cribriform plate region.^{159, 171, 212} Olfactory epithelium can also be found in the middle turbinates and adjacent paranasal sinuses, which may explain the occasional unusual location of these tumors.²¹² Spread of tumor to the paranasal sinuses, anterior cranial fossa, olfactory bulbs, orbits, and cavernous sinus is common.^{64, 118}

Esthesioneuroblastoma occurs in all age groups; however, a bimodal age peak has been noted in the 2nd and 6th decades.¹¹⁰ There is a slight male predominance. The most common clinical presentations are epistaxis, reflecting the vascular nature of the tumor, and unilateral nasal obstruction.^{59, 206} Other less common presenting symptoms include anosmia, sinus pain, and diplopia.⁵⁹

The diagnosis is dependent on the demonstration of neural elements by histochemical or biochemical techniques, with electromicroscopy the most reliable method. Appearance of either an intercellular fibrillary background or Homer-Wright rosettes is diagnostic for esthesioneuroblastoma.^{44, 159, 241} This tumor is often considered "the great imposter" by pathologists, as it can be confused with other small cell malignancies, such as undifferentiated squamous cell carcinoma and lymphoma.²⁴⁹

Esthesioneuroblastomas are typically superior nasal cavity lesions with both bony remodeling and destructive bony growth properties.²⁰⁶ These tumors appear on CT as homogeneous, moderately enhancing, soft tissue masses centered in the superior nasal cavity, with frequent extension into the ethmoid and maxillary sinuses.^{109, 249} MRI signal characteristics and enhancement patterns of esthesioneuroblastomas are nonspecific. Isointense to hypointense T1-weighted and isointense to hyperintense T2-weighted signals relative

to gray matter have been reported. Enhancement patterns on MRI are variable, from mild to marked and homogeneous or heterogeneous (Fig. 21-20).^{59, 206} Cysts along the intracranial margin of the sinonasal mass on MRI have been reported as highly suggestive of esthesioneuroblastoma.²³⁴

Destructive bony changes are usually best evaluated with coronal CT; however, the changes are typically not subtle and MRI can easily detect this finding.²⁰⁶ Calcification, a finding reported as suggestive of esthesioneuroblastoma, can best be seen on CT; however, it is often difficult to distinguish true calcification from residual bony destruction with this tumor.^{59, 234} Coronal, postcontrast MRI images are best for the evaluation of intracranial extension of disease (25% to 30% of cases) and extension of disease into the orbits or paranasal sinuses (40% of cases).^{59, 234, 249} Coronal postcontrast, T1-weighted MRI is useful in the differentiation of nonenhancing obstructive sinus disease from enhancing tumor or recurrent disease.^{59, 206}

Hematogeneous metastasis to the cervical lymph node occurs in 17% of patients at presentation. Thus, if cervical lymphadenopathy is present clinically, CT or MRI of the neck should be performed for evaluation of metastatic disease.

More widespread disease to lungs, bone, and liver occur in 14 to 20% of patients. This is unusual at presentation and more commonly occurs with relapse of disease.^{64, 118, 206, 249}

Treatment is determined by stage of disease at presentation, with most patients undergoing surgical resection and adjuvant radiotherapy.²⁰⁶ The 2-year survival rate is 88%.¹⁴⁰

Figure 21-20. Esthesioneuroblastoma. Coronal T1-weighted postcontrast MRI scan. Marked enhancement of the mass is filling most of the nasal cavity. Intracranial extension is noted within the mass as it extends into the floor of the anterior cranial fossa on the left (arrowhead).

Vascular Malformations (Vasoformative Lesions)

In the past, there had been widespread use of different terminology regarding vascular and lymphatic malformations of the head and neck in children. In 1982, Mulliken and Glowacki proposed a classification of hemangiomas and vascular malformations based on cellular turnover, histology, natural history, and physical findings. The two major categories in this classification system are (1) hemangioma of infancy and (2) vascular malformation.¹⁶⁹

Hemangioma of infancy behaves predictably. These masses appear in infancy, increase in size secondary to endothelial cell proliferation, and spontaneously involute by adolescence.¹³ Vascular malformations are the result of abnormal development of blood or lymphatic vessels. These lesions increase in size as a child grows, have normal endothelial mitotic activity, and fail to involute.¹⁶⁹ In contrast to hemangiomas of infancy, which are clinically obvious at birth, vascular malformations may not become apparent until late infancy or childhood, even though the lesions are present at birth.¹³ Vascular malformations can also be more complex in composition, with multiple vascular elements present. A rapid increase in size may be seen with infection, trauma, or endocrine changes (pregnancy, puberty).¹⁶⁹

Vascular malformations are categorized according to the dominant component of the malformation: (1) capillary, (2) venous, (3) lymphatic, (4) arterial (with or without fistulas), and (5) combined (capillary venous, lymphaticovenous, arteriovenous [AVM]).¹⁶⁹

Both hemangioma of infancy and vascular malformation can be further classified according to flow characteristics as follows^{13,116}:

- Hemangioma of infancy, venous, and lymphatic malformations—low-flow lesions

- AVMs—high-flow lesions
- Combined malformations—low-flow or high-flow lesions

One report has suggested classifying capillary hemangioma of infancy as a high-flow lesion because of the presence of flow voids within the mass on MRI.¹⁵⁷

On CT, hemangioma of infancy is a well-defined mass of isodense attenuation to muscle, with isointense T1-weighted and hyperintense T2-weighted signal to muscle on MRI.¹³ Flow voids within the lesion on MRI are a helpful secondary finding to distinguish this mass from other soft tissue lesions in infancy.¹⁵⁷ Postcontrast CT and MRI scans show a diffuse, homogeneous enhancement pattern (Fig. 21–21). These masses progressively enlarge over a period of several months before spontaneously involuting. Areas of hyperintense T1-weighted signal on MRI scans may be seen during the period of involution secondary to fatty replacement.^{13,157}

Venous malformations (cavernous hemangiomas) are well-defined, predominantly solid soft tissue masses that can have associated bony remodeling or deformity. These masses tend to cross fascial planes and do not spontaneously involute. On MRI, venous malformations have characteristics of low-flow lesions; thus, they lack intralesional flow voids.^{13,157} They demonstrate intermediate T1-weighted signal and heterogeneous, hyperintense T2-weighted signal to muscle with homogeneous or mildly heterogeneous enhancement after contrast administration (Fig. 21–22).¹³ Heterogeneous signal secondary to intralesional phleboliths (usually hypointense T1-weighted and T2-weighted signal) and venous lakes (hyperintense T2-weighted signal) may be found within the lesion.^{13,157}

AVMs do not typically cause mass effect because of a lack of an underlying supporting stroma within the lesion (Fig. 21–23). Serpiginous flow voids on T1-weighted and T2-weighted sequences and decreased T1-weighted signal secondary to intraosseous extension with marrow involve-

Figure 21–21. Hemangioma of infancy. A, Coronal fast spin-echo (FSE) MRI scan shows a large mass involving the superficial and deep components of the parotid space. The mass has multiple intralesional flow voids and diffusely hyperintense signal. B, Marked enhancement of the mass with intralesional flow voids is noted on this axial T1-weighted postcontrast MRI scan.

ment may be seen. The signal voids correlate with AV shunting present on angiography. Invasive, combined vascular malformations are seen as infiltrative, solid masses with serpiginous flow voids. Intermediate T1-weighted and hyperintense T2-weighted signals are seen with mixed lesions (see Fig. 21-3).¹³

Lymphatic malformations are classified according to the size of the embryonic lymphatic sacs into three types²²:

- Lymphangioma simplex
- Cavernous lymphangioma
- Cystic hygroma

Imaging findings are variable and depend on the degree of vascularity of the lesion, the size of the intralesional cystic spaces, and the presence or absence of hemorrhage within the lesion.

Lymphangioma simplex is composed of very small cystic spaces. This subtype thus can appear as a solid mass on ultrasound, CT, or MRI.

Cavernous lymphangioma has moderate-sized cystic spaces; consequently it has a more typical cystic appearance on imaging with anechoic collections and intervening septations on ultrasound and fluid attenuation spaces on CT.^{74,128} On MRI, these masses follow water signal with hypointense T1-weighted and hyperintense T2-weighted signal to muscle. Enhancement of the septations can occur after contrast administration, however, most of the lesion does not enhance.¹⁴⁷

Cystic hygroma is composed of large, nonenhancing fluid-filled spaces with attenuation values and signal characteristics following water in uncomplicated lesions (Fig. 21-24). Secondary infection or hemorrhage into the mass alters the imaging characteristics, with changes dependent

Figure 21-22. Venous malformation. Axial T2-weighted MRI scan. An irregular mass with heterogeneous hyperintense signal is noted (*curved arrow*), involving the superior compartment of the right masticator space and associated superficial, subcutaneous soft tissues.

Figure 21-23. Arteriovenous malformation. Axial postcontrast CT scan. Multiple areas of vascular enhancement are present in the left masticator space (*curved arrows*) and retromandibular space, with an absence of mass effect.

on the stage of breakdown of the blood products. With infection or hemorrhage into the mass, echogenicity on ultrasound, attenuation on CT, and signal intensity on MRI typically increase, with variable enhancement of the mass and surrounding soft tissues.¹⁴⁷

Angiographically, hemangiomas of infancy are distinguished from vascular malformations by the presence of a well-defined mass demonstrating intense tissue staining in an organized lobular pattern. Angiographic findings of vascular malformations are variable and depend on the predominant vascular channel type. These masses are typically diffuse lesions composed of vessels without intervening tissue stain.³²

There are two primary options in the management of low-flow lesions of the head and neck. Hemangiomas of infancy spontaneously involute, so that conservative therapy with observation is indicated. Low-flow vascular malformations and rapidly growing hemangiomas associated with hemorrhage or ulceration and lesions posing a threat to the airway or vision, may warrant more aggressive therapy. In this case, additional therapeutic options include steroid administration, laser photocoagulation therapy, sclerotherapy, embolization, and surgical resection.¹³

Selective arteriography is indicated for complicated AVMs of the head and neck, because these patients may be candidates for embolization with or without surgical intervention. They should also be evaluated for coagulopathy if hemorrhage is noted in the lesion.^{116,169} Some of the combined vascular malformations, with features of both low and high flow, may be highly invasive and resistant to all forms of therapy.¹¹⁶

Mass-Like Conditions

Fibromatosis Colli

Fibromatosis colli, also referred to as muscular or congenital torticollis, is a benign condition in infants related

Figure 21-24. Lymphatic malformation (cystic hygroma). Axial postcontrast CT scan. *A* and *B*, A large, nonenhancing mass of decreased attenuation is present off the lateral aspect of the right neck with extension to the area of the thoracic inlet. Minimal peripheral enhancement is present.

to the sternocleidomastoid muscle (SCM). There are two main theories regarding the etiologic mechanism. These infants often have a history of breech presentation with forceps delivery. The first theory postulates birth trauma with subsequent intramuscular hematoma and fibrosis as the cause.¹⁰⁷ The second theory attributes the condition to fetal intrauterine malpositioning, with torticollis causing the pseudotumor. Histologic findings of fibrosis without hemorrhage in this condition favor the second theory.^{154,245}

Infants typically present at 2 to 4 weeks of age with torticollis and a firm, nontender palpable neck mass. Parents are often concerned initially, because the mass may increase in size for a few weeks. However, the natural history is regression of the process by 4 to 8 months of age in 80% of infants. There is a right-sided predominance (75%).^{154,245}

The goal of imaging is exclusion of other causes of a mass in the muscle, such as a primary tumor. If the patient is referred for imaging, ultrasound is the imaging modality of choice. Sonographic findings include focal or diffuse enlargement of the SCM, with variable internal echogenicity in contrast to normal muscle.^{50,128} A peripheral rim of decreased echogenicity may also be present. This is thought to represent compressed subjacent normal muscle.⁴² In the appropriate clinical setting, this pattern should allow the imager to make the correct diagnosis. CT and MRI are reserved for cases in which the diagnosis is not confirmed by ultrasound.^{42,81} CT findings include a focally or diffusely enlarged SCM with the area of the “mass” isodense to muscle. If contrast material is administered, the mass demonstrates a variable enhancement pattern. On MRI, the enlarged muscle is isointense on T1-weighted and isointense to slightly hyperintense to muscle on T2-weighted images (Fig. 21-25).

Treatment is directed primarily toward physical therapy. In rare cases, when this treatment is unsuccessful, a muscle release may be performed.

Adenopathy or Adenitis of the Neck

Cervical adenopathy is a very common finding in children, usually related to a developing immune system that

is responding to exposure to multiple new antigens. In most pediatric patients, imaging is not required, since cervical adenopathy is reactive in nature. When a case is atypical in clinical presentation or is refractory to medical treatment or when suppuration is suspected, imaging may be requested. In the case of an inflammatory process, the child typically presents with a painful and tender neck mass with associated cervical nodal masses. In this scenario, the imager specialist should address these primary questions:

- Is the process cellulitis or a drainable fluid collection?
- Is there evidence of complication in the form of vascular compromise, airway compression, or osteomyelitis?

The distinction between cellulitis and a drainable abscess is important; the former is usually treated medically, but the latter typically necessitates surgical intervention.

Sonography is a quick, noninvasive method of evaluating the presence of an abscess, with a reported sensitivity of 90% to 95%.^{130,153} The usual appearance of an abscess is a mass of relatively decreased central echogenicity with variable internal echoes. Peripheral flow around an area of liquefaction on Doppler imaging is present in up to 89% of soft tissue abscesses.¹³⁸ Cellulitis has a more homogeneous or striated appearance on sonography.³¹ The sonographic appearance of nonsuppurative adenitis is multiple, oval-shaped masses, with decreased or variable echogenicity. Scattered Doppler flow can be seen in the hila of nodes.¹²⁸ Although sonography is sensitive in detecting adenopathy and inflammatory masses, it lacks specificity in distinguishing infected congenital cystic masses from suppurative masses.¹³⁸

CT has been used most often in an attempt to make this differentiation. On CT scans, cellulitis appears as an ill-defined area of decreased attenuation with mild, diffuse enhancement and “strandlike” infiltration of surrounding soft tissue. A drainable abscess is seen as a single or multiloculated area of decreased attenuation that conforms to fascial spaces and has surrounding peripheral rim enhancement (Fig. 21-26). Secondary findings of adjacent myositis, infiltration with stranding of surrounding fat, skin thickening, engorgement of veins and lymphatics, and enhancement of fascial planes can also be seen.^{103,178}

Figure 21-25. Fibromatosis colli. *A*, Axial postcontrast CT scan. There is marked asymmetry of the sternocleidomastoid muscles, with the larger muscle on the right. No abnormal enhancement is seen. *B*, Coronal T1-weighted MRI scan. The right sternocleidomastoid muscle is diffusely enlarged, with signal isointense to normal muscle (*curved arrows*).

Figure 21-26. Retropharyngeal abscess. Axial postcontrast CT scan. An oval-shaped area of decreased attenuation is noted in the left retropharyngeal space with faint peripheral enhancement. Displacement of the carotid space laterally and effacement of the parapharyngeal fat are present. Bilateral spinal accessory chain adenopathy (*open arrows*) is noted.

Our experience in a CT study of 32 pediatric patients with deep-neck inflammatory processes found a specificity of approximately 75% in distinguishing abscess from cellulitis. A complete, circumferential ring of enhancement was the most sensitive imaging finding. However, this imaging appearance can also be seen with necrotic nodal disease, infected branchial cleft cysts, necrotic neoplasms, and thrombosed vessels. Thus, pertinent clinical history and findings and laboratory data are crucial elements to assist in sorting the imaging findings.

Inflammatory processes in the neck rarely cross into the mediastinum, secondary to constraints of fascial planes. If an infection is present in the visceral space anteriorly or prevertebral space posteriorly, however, the potential exists for extension into the mediastinum. The pretracheal component of the visceral space extends from the hyoid bone to the level of the aortic arch in the anterior mediastinum. The retrovisceral component of the visceral space and prevertebral space extend from the skull base superiorly to the posterior mediastinum inferiorly.^{101,181} With antibiotic therapy, this complication is rarely encountered today.

Part IV

Imaging of the Spine

Edited by
Jeffrey L. Sunshine

Degenerative Diseases of the Spine

David S. Jacobs

Back pain resulting from degenerative disease of the spine is one of the most common causes of disability in adults of working age. Between 60% and 80% of adults suffer from low back pain at some time in their lives. Medical costs resulting from back pain exceed \$50 billion per year and may be as high as \$100 billion.^{23, 24, 38, 83}

Back pain results from many causes, including degenerative and congenital spinal stenosis, neoplasm, infection, trauma, and inflammatory or arthritic processes. Acquired spinal stenosis due to degenerative joint and disk disease accounts for the vast majority of cases.⁵⁷

The following structures may be responsible for the origin of degenerative spinal stenosis:

1. Bone (spondylolisthesis, spondylolysis, osteophytosis).
2. Ligament (hypertrophy of the spinal ligaments, particularly the ligamentum flavum).
3. Facet joint (facet hypertrophy, synovial cyst).
4. Disk (bulging and herniation).

Most often, acquired narrowing of the spinal canal is due to a combination of bone, ligament, joint, and disk disease. The most common location of these changes is the lumbar spine, followed by the cervical spine. Thoracic disk herniation, formerly thought to be rare, is now being recognized with increased frequency with the advent of magnetic resonance imaging (MRI).⁷⁵

Before the emergence of computed tomography (CT), plain films of the spine, spinal tomography, myelography, and diskography were the primary imaging modalities for the diagnosis of spinal stenosis and disk herniation. CT scans provided a noninvasive, nonoperator-dependent method of direct imaging of the spinal canal without injection of intrathecal contrast. CT was superior to myelography in visualizing lateral foraminal stenoses, disk protrusions, and lateral recess stenosis. In addition, it overcame the myelographic limitation of visualizing lower lumbar narrowing. In the latter case, abundant epidural fat in the lower lumbar spine, particularly at L5, may prevent displacement of the myelographic column by a protruding disk.

Finally, and most important, myelography does not delineate the cause of the narrowing (i.e., disk versus ligamentous versus bony hypertrophy). CT scans can reveal the cause of the pathology directly. Postmyelography CT scans offer even more sensitivity because of the increased contrast between thecal sac, nerve roots, and soft tissues of the spinal column.¹⁹

With the development of MRI, the debate over CT scanning versus myelography became moot. MRI has be-

come the modality of choice in the evaluation of spinal degenerative disease. MRI is superior even to contrast-enhanced CT scans in distinguishing bone, disk, ligament, nerve, thecal sac, and spinal cord. MRI provides multiplanar imaging capability. Pulse sequences can be adjusted to evaluate specific areas of interest or to more accurately define the disease process.

CT does retain some advantage over MRI with regard to bone detail, such as in the evaluation of osteophytes. CT and myelography will remain important in patients who, for technical reasons, cannot enter the MRI scanner (e.g., those with pacemakers or claustrophobia) or in patients whose MRI findings do not correlate with clinical symptoms. Many surgeons are still more comfortable with the bone detail of CT scans as a superior "road map" for the operating room. Additionally, recent technology allows the construction of a "virtual" spine from high-resolution CT images. Superb three-dimensional (3D) images of the spine can be obtained from high-resolution axial data acquired from helical CT scanners. This provides surgeons with a preoperative and intraoperative road map of the surgical site, thus improving accuracy and safety (Fig. 22-1). CT, therefore, still has a major role in the evaluation and management of degenerative spine disease.

Lumbar Spine

Anatomic Considerations

A more extensive discussion of the anatomy of the spine is presented in Chapter 24; however, a brief review of the lumbar diskovertebral complex as it relates to degenerative disease is warranted here.

The spinal canal is formed by the vertebral body anteriorly, the pedicles laterally, the laminae posterolaterally, and the base of the spinous process posteriorly (Fig. 22-2). This arrangement forms a protective ring for the neural tube. At the inferolateral aspect of each vertebra, a bony tunnel, the neural foramen, is appreciated bilaterally. The walls of the foramina are formed by the vertebral pedicle superiorly, the pedicle of the next vertebral body inferiorly, the facets posteriorly, and the diskovertebral junction anteriorly. When viewed sagittally, the foramina have a keyhole appearance and are 5 to 10 mm deep (Fig. 22-3). All of these relationships are important to understand when evaluating spinal stenosis.

Inferior to the termination of the spinal cord at approximately T12-L1, the lumbosacral nerve roots travel in a bundle within the dural sac. As this bundle travels inferi-

Figure 22-1. Lateral (A) and frontal (B) 3D images of the lumbar spine reconstructed from 1.5-mm-thick axial data on a helical CT scanner. Images can be rotated in any direction, thus providing a “virtual” surgical field.

Figure 22-2. Axial postmyelogram CT scan (A) and T1-weighted MR image (B) show the borders of the bony canal. L, lamina; P, pedicle; S, spinous process base; V, vertebral body. Arrows indicate nerve roots in the spinal canal, which is filled with iodinated contrast in A (asterisk).

Figure 22-3. Parasagittal (A) and axial (B) T1-weighted MR images illustrate the neural foramina and its borders. D, disk forming the anterior border; I, inferior facet of the superior vertebra; P, superior and inferior pedicles forming the roof and floor; S, superior facet of lower vertebra; V, vertebra forming the anterior border. Arrows indicate exiting roots surrounded by bright epidural fat; on the parasagittal view (A), the roots exit at the top of the “keyhole,” behind the vertebral portion of the diskovertebral junction. The ligamentum flavum is indicated by asterisks.

only, the most laterally positioned roots leave the group in a wide arc to exit through their respective neural foramina. The roots exit under the pedicle of the vertebra for which they are named. For instance, the L5 root exits under the L5 pedicle. Note that the roots exit through the top of the foraminal “keyhole,” just posterior to the diskovertebral junction (see Fig. 22-3). Several small arteries, veins, and nerves accompany the roots through the foramina. The bottom of the keyhole, which is just posterior to the disk itself, contains primarily fat. The exiting roots are surrounded by a sleeve of cerebrospinal fluid (CSF)-containing dura for a very short distance. This sleeve terminates by fusing with the epineurium of the proximal spinal nerve.

After sending off the exiting nerve roots, the cauda equina continues inferiorly within the dural tube. A new set of roots is now positioned laterally. Before reaching the next set of neural foramina, these roots travel separately from the group within the *lateral recesses*. These are small anterolateral niches medial to the vertebral pedicles. As the roots reach the next diskovertebral junction, the process is repeated (Fig. 22-4).

On axial images of the diskovertebral junction, epidural fat lies concentrically around the thecal sac, surrounds exiting nerve roots, and continues into the neural foramina. The vertebral body and disk are seen anteriorly. Posterolateral to the thecal sac are the *facets*. The superior facet of the lower vertebral body lies anterior to the inferior facet of the body above. The facets are continuous with the

laminae that fuse in the midline to form the base of the spinous process (see Figs. 22-2 to 22-4).

The synovial-lined diarthrodial facet joints lie in an oblique parasagittal plane. This plane is relatively coronally oriented in the upper lumbar spine but more sagittally oriented at lower levels. Flush against the laminae and facets is the V-shaped ligamentum flavum, which can occasionally hypertrophy enough to cause canal narrowing.

Imaging Techniques

Although MRI has largely replaced CT as the imaging modality of choice for evaluation of the degenerative lumbar spine, CT is still used as the initial imaging modality in many institutions. In disk disease and canal stenosis, for example, studies have shown greater than 80% correlation between MRI and surgical findings in type and location of pathology. Correlation between CT and surgical findings were similar.^{4, 20, 53, 77} Other studies, however, dispute the validity of many of these analyses.³⁹ If the patient cannot enter the MRI equipment for technical reasons or if cost is a factor, high-resolution CT, especially with sagittal reconstruction, provides satisfactory images of the disk, thecal sac, and neural foramina (Fig. 22-5).

When CT is performed after injection of intrathecal contrast material, the contrast between the thecal sac and surrounding structures is improved (Fig. 22-2A), thus increasing the sensitivity of the examination.²⁶ This is an

Figure 22-4. Axial T1-weighted MR image depicts the path of lumbar nerve roots through the canal. *A*, At the midbody level, the preexisting roots (*arrows*) are positioned in the lateral recesses. *B* and *C*, Just inferior to *A* at the superior aspect of the diskovertebral junction, the roots lie within the foramina. *D*, At the inferior aspect of the diskovertebral junction, the roots have already exited the foramina. *E–G*, Postmyelogram CT scan showing the same sequence of events. *d*, disk; *v*, vertebral body. Note epidural fat, bright on T1-weighted MRI and dark on CT scan, surrounding the sac and roots.

Figure 22-5. Sagittally reconstructed CT scan. Same patient as in Figure 22-1. The spinal canal (c) as well as the disk (d) is appreciated. Note excellent bone detail, particularly of the pedicle (P), pars interarticularis (asterisk), and facets (f). s, spinous process.

invasive procedure, however, with the associated risks of iodinated contrast, bleeding, and infection. The multiplanar capability and high soft tissue contrast resolution of MRI provides superior delineation of disk, fat, nerves, ligaments, CSF, and bone without thecal puncture, intravenous (IV) contrast, or radiation exposure. Furthermore, routine CT imaging covers only a limited number of levels and may miss unexpected disease slightly higher or lower than the area of suspected pathology.

If CT is to be the initial imaging modality for evaluation of low back pain, slices 4 to 5 mm thick with 1 mm overlap is a typical protocol (Box 22-1). These slices should be angled parallel to the disk, compensating for the normal lumbar lordosis.

Because approximately 90% of disk herniations occur at L4-5 and L5-S1, with most of the remainder at L3-4, imaging of these levels is usually sufficient.^{25, 32, 33} The slices are preferably contiguous (i.e., not only through the disk but also through the vertebral body). Selective imaging

through the disk and end plate may miss lateral recess stenosis and migrated disk fragments. Both soft tissue and bone windows should be photographed. Additional images can be obtained, depending on the clinical circumstances. Sagittal or coronal reconstruction may help in evaluation of suspected spondylolysis or spondylolisthesis (see Fig. 22-5). For useful reconstructions, however, usually thin-section images are required. If CT scans are performed after myelography, the same techniques are used. However, my preference is to image the entire lumbar spine from L1 through S1 after myelography. Although degenerative disease of the upper lumbar spine is less common, there is only "one chance" to image the spine while the contrast material is in the thecal sac. Therefore, after myelography, I am unwilling to risk missing lesions in the upper lumbar region.

The osseous anatomy of the lumbar spine is best seen with wide ("bone") window settings. This is helpful for evaluation of osteophytes, fractures, spondylolysis, and facets. Narrower (soft tissue) window settings help to differentiate disk (80 to 120 Hounsfield units [HU]) from dural sac/nerve roots (0 to 60 HU). Epidural fat (-50 to -100 HU) is also well seen on these settings. The *ligamentum flavum* is seen as a soft-tissue-density structure flush against the anterior rims of the laminae and facets (Fig. 22-6).

MRI provides an abundance of choices for spine imaging. Pulse sequences can vary considerably from institution to institution, depending on the type of scanner, MRI vendor, imaging time available, and the individual preferences of the radiologist. There is no one best way to image the spine.

At our institution, MRI of the lumbar spine is performed

Box 22-1. Routine CT Scans of Lumbar Degenerative Disease

- Axial contiguous images from L3 to S1 (begin more superiorly if higher levels are of concern)
- Slice thickness = 4 mm, intersection gap = 3-4 mm
- Intrathecal contrast optional but preferable
- Both wide and narrow window settings
- Sagittal reconstructions if spondylolysis or spondylolisthesis is suspected

Figure 22-6. Axial CT scan using wide (bone) windows (W, 1450, L, 100) (A) and narrow (soft tissue) windows (W, 400; L, 40) (B). Bone detail is better on the wide window settings. The cortex (black arrow) and marrow (asterisk) can best be distinguished with wide windows. However, contrast between the disk (d), epidural fat (white arrow), ligamentum flavum (l), and canal (c) are best seen with narrow windows. C, Iohexol accentuates the contrast between the sac and the surrounding structures.

in both the sagittal and axial planes. The sagittal examination provides information on vertebral alignment and integrity of the vertebral bodies and pars and a general overview of the thecal sac, cauda equina, and nerve roots. The nerve roots within the neural foramina are well visualized on sagittal images. The overall marrow signal is also best evaluated in this plane. Any abnormality on sagittal views should be confirmed on axial views and vice versa. The sagittal plane should include the conus down to at least the level of S1.

At our institution, we obtain all scans by using *fast spin-echo* (FSE) sequences. FSE is a variant of the *rapid acquisition relaxation-enhanced* (RARE) pulse sequence.⁷⁹ This method minimizes imaging time in spine patients, who are often quite uncomfortable lying in one position for any length of time. Additionally, because the FSE sequences take less time, they allow for higher-resolution scans with higher matrices.

Our protocol consists of a set of sagittal and axial FSE T1-weighted images as well as sagittal and axial FSE T2-weighted images (Box 22-2). Sagittal views should cover the entire width of the spine from foramen to foramen. Axial views should be obtained parallel to the plane of the disk space. It is preferable that the axials cover not only the disk space but also as much of the adjacent vertebral body as possible. This is because disk herniations may extend or migrate well beyond the confines of the interspace and may be missed if they are not covered on axial views.

T1-weighted images provide the best anatomic information because the bright epidural fat outlines the normal, darker structures of the spine and spinal canal. T1-weighted images provide optimal contrast between these structures. Moreover, because vertebral marrow has a significant amount of fat, the osseous anatomy is well visualized on T1 sequences (Fig. 22-7A; see Fig. 22-4). Any infiltrative pathology of the marrow (e.g., a neoplasm) can be seen as abnormal low signal within the bright vertebral fat. Marrow is also bright on FSE T2-weighted sequences (less so on

standard T2-weighted, spin-echo sequences). Most pathologic processes, such as neoplasms, are also bright on these sequences and thus may “blend in” with the normal fat and may be missed on these images.

On T1-weighted images, bone is of intermediate to high signal intensity, depending on the degree of fatty marrow. Low signal intensity in bone suggests pathologic infiltration. Disks reflect intermediate signal intensity. The nerve roots, which also reflect intermediate signal intensity, are surrounded by low-signal-intensity CSF, which in turn is enveloped by high-signal fat. On T1-weighted images, ligamentum flavum reflects intermediate to low-signal intensity (see Figs. 22-2 to 22-4).

Box 22-2. Example of Routine MRI for Lumbar Degenerative Disease

1. Sagittal fast spin-echo, T1-weighted image to include conus to S1
 - a. Field of view = 28 cm, slice thickness = 4–5 mm, intersection gap = 1 mm, matrix = 256 × 512
2. Sagittal fast spin-echo, T2-weighted image
 - a. Field of view = 28 cm, thickness = 4–5 mm, intersection gap = 1 mm, matrix = 320 × 512
3. Axial fast spin-echo, T1-weighted image to include L2 through S1
 - a. Field of view = 20 cm, slice thickness = 4 mm, intersection gap = 1 mm, matrix = 256 × 256
 - b. Axial views obtained parallel to the plane of the disk space
 - c. Extra-axial views performed through any abnormality seen at any level
4. Axial fast spin-echo, T2-weighted image
 - a. Field of view = 20 cm, thickness = 4–5 mm, intersection gap = 1 mm, matrix = 256 × 256
5. If postoperative spine, repeat sagittal and axial fast spin-echo, T1-weighted images after gadolinium administration

Figure 22-7. Spinous anatomy.

A, Sagittal T1-weighted (TR = 700 msec, TE_{eff} = 12 msec, ETL = 4) MR image. Marrow fat is brighter than the water-filled disk. Nerve roots (*black arrows*) are slightly hyperintense to the dark cerebrospinal fluid (*white arrows*).

B–D, Various T2-like MRI sequences. B, Standard proton-density (TR = 2700 msec, TE = 20 msec). C, Standard T2 (TR = 2000 msec, TE = 80 msec). D, Fast spin-echo, T2-weighted (TR = 4000, TE_{eff} = 108 msec, ETL = 16) MR image.

E, Short tau inversion recovery (STIR) sequence, used for fat suppression.

In general, the water-filled disk is brighter than bone on T2-weighted sequences. However, the contrast between various structures varies, depending on the sequence used. The “internuclear cleft” (*asterisk*), a normal structure within the disk, is best seen on the T2-like images. Note the darkened fat of the vertebral marrow on the STIR sequence relative to all the other sequences. ETL, echo train length; TE_{eff}, effective echo time; TR, repetition time.

T2-weighted images optimize contrast between disk, bone, and CSF. T2-weighted images and many of the gradient-echo sequences make the CSF “myelographically” bright and the bone darker, which helps reveal the effects of osteophytes and bony hypertrophy on the thecal sac, as noted previously. Unlike standard spin-echo images,

fat remains bright on FSE sequences. FSE sequences can therefore decrease contrast. This can sometimes decrease contrast between the bright spinal fluid and epidural fat. If necessary, fat-suppressed images can be used to ameliorate this problem. We do not find this routinely necessary unless bony neoplasm is suspected. The differentiation between

disk and bone is poorer on T2-weighted images and on gradient-echo sequences. Therefore, the imaging specialist should pay careful attention to both T1-weighted and T2-weighted sequences when analyzing the images.

Nondiskogenic Spinal Stenosis

Pathogenesis

Even in the absence of disk herniation, a combination of facet overgrowth and osteophyte formation at the vertebral end plates can lead to spinal stenosis. These changes are generally referred to as *spondylosis*.

The pathogenesis of spondylosis is believed to be due to recurrent rotational forces on the diskovertebral junction during cyclic axial loading. This results in thinning of the cartilaginous end plate, disk resorption, and consequent disk thinning. Stresses are then redistributed to the bone, leading to facet hypertrophy and end-plate osteophyte formation. Facet changes are exacerbated by repeated synovial

irritation.⁵⁶ As the inferior and superior facets grind one upon another, the vertebral body becomes predisposed to either anterior (anterolisthesis) or posterior (retrolisthesis) slippage on the vertebra inferior to it.

The final result of these degenerative osteoarthritic changes is stenosis of the spinal canal, neural foramina, or lateral recesses or a combination of these.^{9, 18, 22, 36, 40, 42} This causes nerve root compression as well as other pathophysiologic events, leading to the pain commonly known as *sciatica*.⁶⁰ The specific focus of narrowing depends on the structure involved.

Facet Hypertrophy

With repeated strains on the apophyseal joints, the articular cartilage is gradually stripped away and the underlying bone hypertrophies. Because the facets make up part of the wall of the neural foramen, foraminal narrowing can result, impinging on the exiting nerve roots (Fig. 22-8). These changes predominate in the lower lumbar spine.⁶⁴

Figure 22-8. A, Facet hypertrophy. Postmyelogram CT scans shows massive facet hypertrophy bilaterally. Arrow indicates facet encroachment on the thecal sac. Compare with normal facets in Figure 22-4G. B, T2-weighted MR image shows hypertrophied facets (f) and ligamentum flavum (l) encroaching on the foramina, (arrows), obliterating the foraminal fat and severely narrowing the canal (c). C, T2-weighted MR image shows asymmetrical facet hypertrophy. The left facet exerts mass effect on the canal (black arrow). Compare with normal facets in Figures 22-3B and 22-4C and D.

Figure 22-9. Osteophytes. *A* and *B*, Postmyelogram CT scans show osteophytes (arrows) encroaching on the canal and foramina. *C*, Sagittal T1-weighted MR image shows osteophytes (arrows) encroaching on the canal.

Osteophytes

With advancing age, osteophytosis of the lumbar vertebral end plates becomes increasingly common. The prevalence of osteophytes in patients aged 50 years and older is approximately 60% to 80%. The exact mechanism of osteophyte formation is debated, but it, too, probably results from complex stresses on the spine. Osteophytes are more common in men⁶⁴ and in individuals who are engaged in heavy physical labor. Depending on size, shape, and location, osteophytes can narrow or focally impinge on any part of the neural canal (Fig. 22-9).

Spondylolisthesis

As facets constantly grind upon one another they become smooth and “slippery.” Thus, the ability of the superior (anterior) facet of a vertebral body to hold in check the inferior (posterior) facet of the vertebral body above becomes deficient. The upper vertebral body gradually slips forward over the lower one (Fig. 22-10). This is most common at L4-5, where the facets are oriented more sagittally than at any other level and are therefore most predisposed to slippage.⁶⁴

Spondylolisthesis is divided into four grades of severity

Figure 22-10. *A*, Spondylolisthesis. Sagittal T2-weighted image of spondylolisthesis of the L4 vertebra off L5. Note the severe canal stenosis caused by the slippage. The disk (closed arrow) is exposed by the slippage of L4, giving the false impression of herniation (“pseudoherniation”). The posterior longitudinal ligament (open arrow) is displaced by the spondylolisthesis. *B*, Axial scan at the L4-5 level of the same patient as in *A*. Note severe stenosis of the canal (asterisk).

according to whether 25%, 50%, 75%, or 100% of a vertebral body has slipped forward upon its neighbor. As slippage becomes more severe, the spinal canal and/or the neural foramina can progressively narrow at that level, producing symptoms.

Fractures of the pars interarticularis (spondylolysis) are not prerequisites for degenerative spondylolisthesis.

Ligamentum Flavum Hypertrophy

The reasons for ligamentum flavum thickening are not completely understood, but they are probably related to mechanical instability and asymmetrical stresses on the facets. Because this structure lies flush against the posterior wall of the bony canal, ligamentum flavum hypertrophy contributes to canal narrowing (Figs. 22-11 and 22-12).⁶⁴

Lateral Recess Stenosis

Bony overgrowth of the lateral recesses can occur as part of the degenerative process, resulting in entrapment of the lateral (*preexisting*) roots. Alternatively, when herniated disk material extrudes up or down into the lateral recesses, the preexisting roots can become compromised. Facet and ligamentum flavum hypertrophy can also contribute to lateral recess stenosis (see Fig. 22-12).

Synovial Cysts

With chronic irritation, tears can develop in the capsule of the facet joint and fluid can migrate through the capsule into the epidural space and form a cyst (Fig. 22-13). The cysts are usually of simple fluid intensity (dark on T1-weighted and bright on T2-weighted images); however,

Figure 22-11. Ligamentum flavum hypertrophy. A, Axial T1-weighted MR image. The ligament (L) is markedly enlarged, but the capacious canal is not compromised in this case. B, Postmyelogram CT scan in another patient. The contrast column (*circle*) is compressed by hypertrophied ligamentum flavum (*arrowheads*) as well as by herniated disk (*arrow*). Note also lateral recess stenosis, caused by a hypertrophied facet (*open arrow*). C, T1-weighted axial MR image shows unilateral ligamentum flavum hypertrophy in the same patient as in Figure 22-8B but at a different level. The hypertrophied right ligamentum flavum (L) impinges on the canal. See also Figures 22-8B and 22-12B.

Figure 22-12. A, Lateral recess stenosis. CT scan shows preexisting nerve roots (arrows) within tiny lateral recesses. This patient with achondroplasia had nondegenerative congenital spinal stenosis. Compare with normal lateral recesses in Figure 22-4E. B, T2-weighted scan, same patient as in Figure 22-11C. The hypertrophied ligamentum flavum has obliterated the right lateral recess (white arrow). The left lateral recess (black arrow) is also narrowed by the hypertrophied facet, but some epidural fat can still be seen.

they may be brighter on T1-weighted and darker on T2-weighted images if the fluid contains proteins. These cysts can exert mass effect on or can narrow the canal, resulting in nerve-root symptoms. Synovial cysts can be resected surgically or may be aspirated under CT guidance.⁴⁶

Other Causes of Stenosis

Disk bulges or herniations (see later, “Bulging and Herniated Disks”) can narrow any part of the canal or foramina. Stenosis can be unilateral, bilateral, or diffuse.

Although lumbar degenerative disease typically begins at L4-L5 and L5-S1, the entire lumbar spine can become involved as mechanical stresses gradually shift cephalad.

Accurate assessment of the normal dimensions of the spinal canal can be difficult because of wide variations caused by body habitus and age. On lumbar CT scans, an anteroposterior dimension of less than 11.5 mm (measured from disk-vertebral body edge to the base of spinous process), an interpediculate distance of less than 16 mm, and a

Figure 22-13. Synovial cyst. T1-weighted (A) and T2-weighted (B) images of a left synovial cyst (arrows). In this case, the synovial fluid is isointense to cerebrospinal fluid on both sequences. The cyst emanates from fluid (f) in the joint capsules.

cross-sectional area smaller than 1.45 mm^2 are considered

Clinical Considerations

The clinical presentation of lumbar spinal stenosis usually begins with a history of chronic low back, bilateral-buttock, and thigh pain. If nerve-root compression is a feature, the pain may radiate down an extremity. Numbness and weakness, as well as coldness, tingling, and burning, may also occur. Many patients describe transient motor deficits.

The pain is more vague and poorly localized than that associated with a herniated disk. In fact, degenerative spinal stenosis may mimic peripheral vascular disease, simulating the symptoms of vascular claudication. In contrast to vascular claudication, however, the patient with spinal stenosis assumes a chronic stooped, flexed position (simian posture) in order to alleviate the pain. In patients with vascular claudication, pain is alleviated by standing and resting. In patients with spinal stenosis, the pain takes longer to subside, and walking distance before the onset of pain is more variable.

Physical changes resulting from peripheral vascular disease, such as decreased pulses and skin breakdown, are not present.^{18, 27, 29, 41, 57, 62} On physical examination, the lumbar lordotic curve becomes straightened or reversed and pain may be reproduced on extension. Decreased lumbosacral motion is noted. It is not common to elicit motor or sensory deficits. In most cases, abnormal reflexes corresponding to L4 and L5 nerve roots are noted. Positive straight leg raising may be found. Objective weakness of the muscles may be supplied by the L5 and S1 nerves.^{18, 27, 29, 41, 44, 62}

The pathophysiology of clinical symptoms related to spinal stenosis is complex, controversial, and not well understood. Most investigators believe that direct compression of nerve roots plays a major role in pain production, although arterial and venous obstruction may also be important. Some suggest that pseudoclaudication may be related to true vascular insufficiency of nerve roots.⁵⁷ Release of irritating chemicals by surrounding structures, nerve edema, chronic impairment of axonal transport, and intra-neural microcirculation insufficiency may also be factors.⁶⁰

Diskogenic Spinal Stenosis

The three major components of the intervertebral disk are the nucleus pulposus, the annulus fibrosus, and the end

plate. The nucleus pulposus is the jelly-like core of the disk, containing 90% water mixed with delicate fibrous strands. The nucleus merges with the surrounding capsule, the collagenous annulus fibrosus. The cartilaginous end plate fuses the inferior and superior surfaces of the vertebral body to the disk (Fig. 22-14). The components of the disk complex optimize shock absorption from mechanical stresses on the vertebral column.

The normal intervertebral disk on CT scans are approximately 50 to 100 HU, which is somewhat denser than the surrounding ligaments and much denser than epidural fat and the fluid-filled thecal sac. This makes the disk easily distinguishable from neighboring structures, particularly in the case of disk herniation.

On T1-weighted MR images, the disk is a fairly homogeneous structure, isointense to muscle. On images with a long repetition time (TR), the disk becomes brighter because of its water content. On T2-weighted images, the nucleus pulposus, which is more hydrated than the annulus fibrosus, becomes even brighter than the annulus.

Pathogenesis

The pathogenesis of disk degeneration is complex and not well understood. End-plate and disk degeneration is probably a normal consequence of the aging process. By age 50 years, 85% to 95% of adults show evidence of degenerative disk disease at autopsy.⁶³ The cartilaginous end plate becomes thinner. The nucleus pulposus and, to a lesser degree, the annulus fibrosus lose up to 70% of their water content. The disk tissue also undergoes biochemical changes with respect to its collagen and proteoglycan content. The entire volume of the disk decreases with aging.^{1, 11, 16} Annular fibers become stretched, leading to disk bulging (which is usually not significant unless the canal is already small). These changes occur most frequently in the parts of the lumbar spine most subjected to mechanical stresses (i.e., L4-5 and L5-S1).

Whether normal disk aging plays a predisposing role is unclear, but the sequence of events in disk herniation appears to be as follows. The annulus becomes frayed during repeated flexional and rotational forces, resulting in radial and concentrically oriented fissures in the annulus. This then predisposes the nucleus to further degeneration and subsequent herniation into and then through the annular fibers.⁵¹ Although central disk herniations are by no means rare, disks tend to herniate posterolaterally because the posterior longitudinal ligament and annular fibers are thickest and strongest in the midline and thinner laterally.

Figure 22-14. Disk anatomy. The jelly-like nucleus pulposus is encircled by the fibers of the annulus fibrosus. The cartilaginous end plate, which fuses with the vertebral body, covers the superior and inferior disk surfaces. (Modified from Modic MT: *Magnetic Resonance Imaging of the Spine*. St. Louis, Mosby-Year Book, 1989.)

Figure 22-15. Type I end-plate changes. A, T1-weighted MR image shows hypointensity of the inferior L2 and superior L3 end plates (*arrows*). B, T2-weighted MR image shows that the end plates have become hyperintense. This is the earliest stage of disk degeneration. The lower lumbar disks are dark on the T2-weighted scan because they have become dehydrated from degeneration. Note small Schmorl's nodes (*asterisks*).

Figure 22-16. Type II end-plate changes. T1-weighted (A) and fast spin-echo, T2-weighted (B) MR images; show fatty end plates (*arrows*), which are hyperintense on T1-weighted and fast spin-echo, T2-weighted images.

Figure 22-17. Type III end-plate changes. T1-weighted (A) and T2-weighted (B) MR images show hypointensity of the inferior L3 and superior L4 end plates on both sequences (arrows).

Radiographic Changes

The earliest radiographically visible changes of intervertebral disk degeneration are those that occur at the end plate. These are best seen on MRI. Three types of end-plate changes have been described^{17, 56}:

Type I changes demonstrate low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 22-15). This stage is believed to reflect replacement of the end-plate marrow with vascular fibrous tissue in response to chronic “injury.”

Type II changes, the next stage, show high signal intensity on T1-weighted and on FSE T2-weighted images (Fig. 22-16). This stage represents replacement of the end-plate marrow with fatty tissue. (On standard spin-echo,

T2-weighted images, the fatty end plates thus become slightly darker.) Type II changes tend to remain stable with time.

Type III changes, or the final stage if it occurs, are represented by low signal intensity on both T1-weighted and T2-weighted images (Fig. 22-17). This stage correlates with bony sclerosis seen on CT scans and plain films of severely degenerated end plates. This is the only end-plate change visible on CT scans or radiographs. Whether these end-plate changes have any prognostic significance has not been established; however, they are part of the normal aging process and must not be confused with other pathologic processes, such as tumor and infection (Fig. 22-18).

Bulging and Herniated Disks

Classification

The most important step in the analysis of the degenerative lumbar spine—after the vertebrae, end plates, ligaments, and joints—is the disk itself. As mentioned, the intervertebral disk is made up of a jelly-like nucleus pulposus, surrounded by a tough, fibrous annulus fibrosus. Unfortunately, no universally accepted classification of disk herniation exists. The one presented here⁵¹ may differ from those offered by other texts and institutions.^{47, 49}

Abnormal disks can be classified as *bulging* or *herniated*. A *herniated disk* can be subclassified as (1) protruded, (2) extruded, or (3) sequestered.

Bulging Disk

An *annular bulge* represents an extension of the disk margin beyond the confines of the adjacent vertebral end plate. The annular fibers are stretched but intact. The disk bulges diffusely around the posterior (and sometimes lateral) aspects of the end plate (Figs. 22-19 and 22-20). This does not usually lead to clinical symptoms unless the spinal canal is already congenitally small or narrow owing to spondylosis.

Protruded Disk

When some of the inner fibers of the annulus tear but the outer layers remain intact, the nucleus can focally

Figure 22-18. T1-weighted (A) and T2-weighted (B) MR images show end-plate changes of varying stages. The resulting marrow heterogeneity is easily confused with bone metastases.

Figure 22-19. Illustration of a bulging disk. The disk bulges diffusely beyond the vertebral body margin. The annular fibers are stretched but completely intact. (Modified from Modic MT: *Magnetic Resonance Imaging of the Spine*. St. Louis, Mosby-Year Book, 1989.)

Figure 22-21. Illustration of disk protrusion. A portion of nucleus pulposus herniates focally through a rent in the inner annular fibers. The outer annular fibers are intact. (Modified from Modic MT: *Magnetic Resonance Imaging of the Spine*. St. Louis, Mosby-Year Book, 1989.)

herniate through the inner tear. This is the simplest (and probably earliest) type of disk herniation and is called a *disk protrusion* (Fig. 22-21).

Disk herniation is distinguished from annular bulge by its focality. Whereas a disk usually bulges fairly uniformly along its margins, a disk herniates through one particular spot—the annular tear. The signal intensity (on MRI) and density (on CT scans) of the protruded segment are generally, but not invariably, the same as those of the nonherniated portion.

Extruded Disk

A *disk extrusion* occurs when the nucleus pulposus herniates through a complete tear of the annulus fibrosus and is contained only by the posterior longitudinal ligament (Fig. 22-22). The herniated segment, however, remains attached to the parent disk but may extend cephalad or caudad. It can be difficult to differentiate between a disk

protrusion and extrusion when the amount of herniated disk is small. This distinction, however, is not clinically significant; it is more important to recognize that these are simply different degrees of herniation and that the significance of a herniated disk is its effect on the spinal canal and nerve roots (Figs. 22-23 and 22-24).

Sequestered Disk

Finally, when an extruded nucleus breaks free of the parent disk, it is termed a *sequestered disk* or *free fragment* (Fig. 22-25). The sequestered portion may or may not be confined by the posterior longitudinal ligament. In fact, it may migrate inferiorly or superiorly to a different interspace or, in rare cases, may even penetrate the dura. Free fragments also tend to resemble the parent disk on both CT scans and on short TR MR images (Fig. 22-26).

On long TR or gradient-echo MR images, sequestered disks may be of higher signal intensity than the disk of

Figure 22-20. Disk bulge. Postmyelogram CT scan (A) and T1-weighted (B) MR image show disk margins (long arrows) diffusely bulging beyond the bone margins (short arrows).

EXTRUSION

Figure 22-22. Illustration of disk extrusion. The nucleus has herniated through a complete annular tear but remains connected to the parent disk. (Modified from Modic MT: *Magnetic Resonance Imaging of the Spine*. St. Louis, Mosby-Year Book, 1989.)

origin. The most important distinction, however, is the lack of a connection between the extruded component and the parent disk. This is better appreciated on MR sagittal views than on axial views. On CT scans, sagittal reconstructions are often necessary to confirm the presence of a free fragment. Because there is no connection to the parent disk, free fragments can be confused with neoplasm, abscess, or postoperative epidural fibrosis.

Clinical Considerations

The clinical presentation of disk herniation is different than that of nondiskogenic spinal stenosis, in that it tends to be acute and occurs in younger individuals between ages 30 and 45. The inciting event is usually a fall, sudden lifting, or rotation. Sometimes it occurs spontaneously.

The pain usually begins in the lower back, and the patient flexes anteriorly or laterally to reduce the pain. Pain is exacerbated by standing, sitting, or by increased CSF pressure induced by coughing, sneezing, or bowel movements. Because the most commonly compressed roots are

Figure 22-23. Various disk herniations on a postmyelogram CT scan. A, Small disk herniation (arrows) impinging on the spinal canal. Note focality. B, Larger herniation (arrows) with mass effect on the canal. C, Larger herniation encroaching on right neural foramen (white arrows). An osteophyte (black arrow) is encroaching on the left foramen.

Figure 22-24. Various disk herniations as shown with MRI.

- B, Sagittal T2-weighted MRI of the same patient. Disk herniation (arrow) and displacement of the posterior longitudinal ligament (arrowheads) by the disk.
- C, Axial T1-weighted scan of the same patient. Arrows indicate the herniated disk.
- D, Axial T2-weighted scan in the same patient. Note displacement of the right S1 nerve root (closed arrow) by the disk. The open arrow indicates the normal left S1 nerve root.

Figure 22-24 Continued

E–G, Multiple disk herniations in a different patient. T2-weighted right parasagittal (*E*) and midline sagittal (*F*) images. The right L4-5 foramen and nerve root (arrow in *E*) are crowded by an L4-5 disk herniation. Note how the L1-2 herniation extends superiorly behind the posterior longitudinal ligament (arrow in *F*). *G*, Axial T1-weighted view of L4-5 herniation. The disk presses on and displaces the intraforaminal right L4 root. The herniated disk and *G*, displaced root form a large soft tissue mass (white arrow). Note the normal left L4 root (black arrow) with surrounding fat.

H and *I*, Sagittal (*H*) and axial (*I*) T2-weighted MR images of a huge herniated disk lying behind the L4 vertebral body. The disk is so large that one cannot tell if it emanates from the L3-4 or the L4-5 interspace. The disk is probably *sequestered*, or broken off from the native disk.

HERNIATION

Figure 22-25. Illustration of a sequestered disk. Disk material has herniated through a complete annular tear and has broken off from the parent disk. The disk fragment can migrate freely. (Modified from Modic MT: *Magnetic Resonance Imaging of the Spine*. St. Louis, Mosby-Year Book, 1989.)

L5 and S1, pain radiates down the lower extremity in these radicular distributions (Fig. 22-27). Paresthesias may also be a feature. The radiculopathy has both a mechanical component, owing to compression by the herniated disk, and an inflammatory component, owing to nerve root edema.

Medical treatment, usually with steroids, anti-inflammatory agents, and a regimen of physical therapy, can reverse the inflammatory component and alleviate symptoms. If pain persists as a result of the mechanical component, surgery may be necessary.⁴⁷

Postoperative Lumbar Spine

Imaging of Complications

Scarring and Recurrent Disk Herniation

A variety of surgical techniques are available for treatment of spinal stenosis and disk disease. The surgeon may remove a variable amount of bone from the posterior elements to expose an area for *discectomy*, spinal canal *decompression*, or both. In a *laminectomy*, much of the

vertebral body lamina is removed (Fig. 22-28). Sometimes the exposure is widened by removal of a variable amount of facet joint for better visualization and decompression. In a *laminotomy*, only a small amount of lamina is removed near a herniated disk for adequate exposure.

On CT and MRI, laminectomy sites are fairly obvious because of the bone removal involved. In a *microdiscectomy*, however, only a tiny bit of lamina is removed and sometimes the operative site is difficult to locate on CT scans or MR images. Before the advent of MRI, contrast-enhanced CT scans were the preferred method of evaluating the postoperative spine.³⁰ This method has essentially been replaced by MRI because of its superior ability to differentiate postoperative soft tissue changes (e.g., *scarring* versus *recurrent disk herniation*),⁶⁷ its multiplanar capability, and the use of relatively safe contrast agents. MRI changes in the postoperative spine are now well described^{13, 67, 70, 71} and are summarized here.

In the immediate postlaminectomy period, the signal from normal bone and ligament is replaced by edema at the resection site. This is heterogeneously isointense to muscle on T1-weighted images and increased on T2-weighted images. In a purely decompressive laminectomy without discectomy, significant mass effect on the thecal sac is unusual unless a hematoma is present. Between 6 weeks and 6 months after surgery, the postoperative edema is replaced by scar tissue posterior to the thecal sac. The scar appearance can range from low to high signal intensity on T2-weighted images (Fig. 22-29).

If a discectomy is performed with the laminectomy, additional changes related to the discectomy are appreciated. In the early postoperative period, there is edema in the anterior epidural space in addition to disruption of the posterior annular margin due to disk curettage. On T1-weighted images, this is reflected by anterior epidural intermediate signal intensity that may blend with the remaining native disk. On T2-weighted images, this area may be variably hyperintense. This probably results from edema⁶⁷ and possibly even blood.⁶

The imaging specialist must therefore exercise care in

Figure 22-26. Sequestered disk. A, Sagittal MR image shows an L4-5 disk fragment (arrow) lying posterior to the L4 body. B, Axial MR image shows the fragment (arrows) obliterating the L4 root in the right lateral recess and pressing on the thecal sac. See also Figure 22-24H and I.

Figure 22-27. Illustration of lower extremity radiculopathies resulting from common disk herniations.

Figure 22-29. Laminectomy. *A*, Sagittal unenhanced, T1-weighted MR image shows an isointense, posterior epidural scar (*black arrow*). The anterior epidural scar from this L4-5 discectomy is also seen (*white arrow*). Note resection of L5 spinous process. *B*, T2-weighted MR image shows the scar (*arrows*) as hyperintense but heterogeneous. A small, focal fluid collection (*asterisk*) is also visible. This is a normal postoperative finding.

interpreting early postoperative changes because this normal mass effect on the thecal sac may mimic recurrent or residual disk herniation (Fig. 22-30). Furthermore, confusing areas of gadolinium enhancement may be seen in the normal early postoperative spine, including the paraspinal muscles, facet joints, and nerve roots.⁶ Therefore, gadolinium cannot be used for the evaluation of scar versus recurrent disk herniation in the early postoperative period.

The reasons for all of these normal early postoperative changes have not been completely worked out. Therefore, MRI should probably not be used in the early postoperative period unless other complications, such as hematoma, pseudomeningocele, and infection, are suspected. By 6 weeks after surgery, the edema and mass effect subside and the thecal sac margin returns to normal.

In a patient with late postsurgical recurrent back pain, the distinction between recurrent disk herniation and scarring must be made because reoperation on a scar may lead to a poor result with the formation of more scar tissue. Noncontrast MRI is at least equivalent to contrast CT

scanning in distinguishing scar from disk,¹³ with a 79% accuracy rate for noncontrast MRI and a 71% accuracy rate for contrast CT scans in one study.⁷⁸

Scar tissue tends to conform to the shape of, and often to enwrap, the dural sac and exiting nerve roots, and it does not have a definable margin (Fig. 22-31). Mass effect on the thecal sac may or may not be present; however, the dura may actually retract toward the scar.

On non-contrast-enhanced MR images, anterior epidural scar tissue is generally hypointense to isointense to disk on T1-weighted sequences and hyperintense on T2-weighted sequences. Lateral and posterior scar tissue may be somewhat more variable. Herniated disks tend to be contiguous with the native disk space (unless sequestered) and have a definable margin (see Fig. 22-24). Mass effect on the thecal sac is present. Herniated disks tend to be of low signal intensity on all pulse sequences but large, extruded, and sequestered disks can be hyperintense on T2-weighted sequences, making distinction between a disk, a scar, and CSF difficult.⁴⁸ Morphology, rather than signal characteris-

Figure 22-30. Early view of the postoperative spine. T2-weighted image shows apparent severe canal stenosis (*asterisk*) from a soft tissue structure (*arrowhead*), which probably represents soft tissue swelling and blood, but mimics the appearance of disk herniation. Note subligamentous edema (*arrows*), also a normal postoperative finding. The patient was asymptomatic at this particular level.

Figure 22-31. Axial T1-weighted MR image shows an epidural scar (*arrows*) partially encircling and compressing the thecal sac. The posterior margins of the scar are ill defined.

Figure 22-32. Sagittal T1-weighted postoperative MR image shows an apparent recurrent disk herniation (*arrow*) at L4-5. With contrast enhancement, this proved to be scar tissue.

tics, is therefore probably a more useful method of distinguishing a scar from a disk on the noncontrast MRI.^{30, 67} Even so, well-defined scar tissue can mimic a disk herniation on unenhanced MR images (Fig. 22-32).

Gadolinium-enhanced MRI has met with considerable success in differentiating postoperative scarring from recurrent disk herniation. Accuracy of contrast-enhanced MRI has been reported to be as high as 96%.^{31, 74} Scar tissue consistently enhances postoperatively (Fig. 22-33) and continues to enhance months to years after surgery.³¹ A herniated disk should not enhance (Fig. 22-34).

One caveat: Even though anterior epidural scar invariably shows this pattern of consistent enhancement, posterior epidural scar may not. In fact, posterior epidural scar may show a rapid decline in enhancement over a period of months,^{31, 68} although the reason for this is not known.

As noted previously, a herniated disk does not enhance in the immediate postinjection period. If delayed images are obtained, contrast medium may diffuse into the herniated disk from adjacent scar tissue, causing disk enhancement as well. Therefore, care must be taken to complete the enhanced portion of the examination no more than 30 minutes after injection. Gadolinium is particularly useful when a mixture of scar and recurrent disk herniation is found; the enhancing scar can be separated from the nonenhancing, low-signal recurrent disk herniation (Fig. 22-35). However, an enhancing, inflammatory reaction around a herniated disk is a common occurrence, even in the absence of prior surgery. This peridiskal reaction may actually be prominent enough to obscure a small herniation that it surrounds, thus masking it and mimicking pure scar tissue.

These enhancement characteristics generally apply to patients in the late postoperative period (>6 weeks after surgery). Scar tissue has been shown to enhance in the early postoperative period.⁶ As mentioned, however, differentiation of this enhancement from the myriad normal immediate postoperative changes may be difficult. The enhancement of epidural scar is probably related to "leaky

Figure 22-33. Same patient as in Figure 22-32. *A*, Axial unenhanced T1-weighted MR image shows an apparent recurrent disk herniation (arrow). *B*, After gadolinium administration, the scar tissue (arrow) enhances intensely, wraps the left L5 root, and compresses the thecal sac. No evidence of disk herniation is seen. Axial unenhanced (*C*) and enhanced (*D*) T1-weighted MR images demonstrate postoperative scar (arrows) in another patient. Note small, nonenhancing postoperative fluid collection (asterisk), which can be seen only after contrast administration. This is a common postoperative finding.

Figure 22-34. Postoperative disk herniation. *A*, Sagittal unenhanced MR image shows major disk herniation. *B*, Axial MR image after gadolinium administration shows no disk enhancement (arrows).

Figure 22-35. Disk herniation. *A*, Postoperative sagittal unenhanced, T1-weighted MR image. Recurrent disk herniation (arrow) is indistinguishable from scarring (arrowheads). *B*, Nonenhancing recurrent disk herniation (arrow) now stands out from the surrounding postoperative scar (arrowheads). The intensely enhancing bright rim around the disk is not a postoperative scar but, instead, peridiskal inflammation, which can be seen even on nonoperated disk herniations. *n*, nerve root. *C*, Axial enhanced T1-weighted MR image in the same patient shows recurrent disk herniation with surrounding peridiskal inflammation (closed arrows). Open arrows indicate a postoperative scar.

vascularity,"⁶⁹ which can persist years after surgery; in contrast, the herniated disk is avascular.

In summary, a recurrent herniated disk is an avascular, well-defined, low-intensity mass that does not enhance on early postinjection images. It has a well-defined margin and is usually located in the anterior epidural space contiguous with or near the native disk space. An epidural scar

is a vascular structure with ill-defined margins that tends to encircle the thecal sac and roots. Anteriorly, it consistently enhances even years after surgery. Posterior epidural enhancement may decline over time. Whereas morphology and enhancement are quite reliable in differentiating a disk from a scar, signal characteristics and mass effect may overlap and should be used only as secondary signs.

Figure 22-36. Postoperative bone overgrowth. Postmyelogram CT scan shows severe hypertrophy of posterior elements compressing the spinal canal.

Other Complications

Aside from recurrent disk herniation, several postoperative complications may occur, including:

- Bony stenosis
- Pseudomeningocele
- Arachnoiditis

- Disk space infection
- Epidural abscess

Bony Stenosis

Bony stenosis may account for up to 60% of failed back surgery cases.⁸⁰ Osteophytes and hypertrophic bone vary in MRI signal appearance, depending on degree of marrow content. CT, particularly with intrathecal contrast material, is especially helpful in evaluating canal narrowing resulting from postoperative bone overgrowth (Fig. 22-36).

Pseudomeningocele

A pseudomeningocele is a localized collection of fluid communicating with the thecal sac. This results from an iatrogenic dural tear during surgery.⁸¹ Whereas small postoperative fluid collections along the soft tissues of the incision site may be a normal finding, a pseudomeningocele is not. MRI and CT scans show a saclike area of fluid intensity adjacent to the dura (Fig. 22-37). Blood or debris may be present within the fluid. Differentiation between abscess, postoperative fluid collection, and pseudomeningocele may be difficult. However, pseudomeningocele is likely if a communication between the thecal sac and the collection can be demonstrated, or if, on CT myelography, contrast medium enters the fluid collection.⁶⁷

Arachnoiditis

Arachnoiditis represents an inflammatory reaction in which nerve roots adhere to the thecal sac and to each

Figure 22-37. Pseudomeningocele. A, Postsurgical sagittal T2-weighted MRI shows large pseudomeningocele (PM). The communication (between the arrows) between the pseudomeningocele and the canal (C) is quite large. Compare with small, normal postoperative fluid collection shown in Figure 22-27, B, Axial postoperative CT scan in a different patient shows a large amount of intrathecally injected contrast pooling in a pseudomeningocele. Demonstrating the actual connection between the pseudomeningocele and the thecal sac can be difficult at times and could not be shown in this figure.

other. This can occur after laminectomy and is one of the causes of failed back surgery.¹⁴ Normally, the nerve roots are symmetrically distributed within the dependent portion of the CSF (see Fig. 22-4G). In arachnoiditis, nerve roots clump together centrally or adhere to the dura peripherally. In advanced stages, the lumbar spinal canal is filled with inflammatory soft tissue. These changes are obvious on both MRI² and on CT myelography (Fig. 22-38). Interestingly, enhancement is not a prominent feature.

Disk Space Infection

Postoperative disk space infection and epidural abscess are uncommon but serious postlaminectomy complications. Although diskitis in adults is usually characterized by he-

matogeneous spread, bacterial contamination from disk manipulation can occur.

Disk space infection typically presents as hypointensity on T1-weighted images and as hyperintensity on T2-weighted images in the disk and adjacent end plates, with poor definition of the end plates themselves. These signal changes reflect reactive edema. On T2-weighted images, the internuclear cleft (the normal horizontal band of low signal intensity in the center of the nucleus pulposus) is lost. In disk space infection, the disk and adjacent end plates usually enhance with gadolinium administration (Fig. 22-39).⁷ Despite the myriad early normal postoperative changes in the epidural space, generally no signal intensity or morphologic changes are found in the disk space itself or in the adjacent end plates after uncompli-

Figure 22-38. Arachnoiditis. *A*, Axial postoperative unenhanced T1-weighted MR image shows clumping of nerve roots (*arrows*) within the spinal canal. *B*, Enhanced scan in another postoperative patient shows the nerve roots adhering peripherally to the dura (*arrows*). Note that root enhancement is not a feature. *C*, Postmyelogram CT scan shows nerve roots adhering peripherally to the dura (*arrows*). This gives the appearance of an “empty” thecal sac. *D*, Postmyelogram CT scan shows advanced arachnoiditis. Most of the spinal canal is filled with inflammatory tissue (*arrows*), with only a small amount of contrast noted anteriorly.

Figure 22-39. Postoperative infection.

A, T1-weighted unenhanced MR image of L4-5 diskitis/osteomyelitis. Dark signal (*asterisks*) denotes edema in the vertebral end plates and marrow. The infected disk is conforming to the shape of eroded end plates (*closed arrows*). Abnormal soft tissue is seen in the anterior epidural space (*open arrow*).

B, T1-weighted enhanced MR image in the same patient. The margins of the disk enhance (*closed arrows*) as does the infected anterior epidural soft tissue (*open arrow*).

C, Short tau inversion recovery (STIR) sequence shows the bone edema (*asterisks*) markedly well. Note loss of the internuclear cleft in the infected disk (*closed arrow*) compared with a normal nondegenerated, noninfected disk (*open arrow*).

D, Fast spin-echo, T2-weighted MR image does not show the edema nearly as well as the STIR sequence, which is indispensable for evaluation of osteomyelitis.

cated discectomy.⁷ Therefore, any disk space or end-plate abnormality in the postoperative period should be viewed with suspicion.

Several problems occur, however, in differentiating both degenerated disks and normal postoperative disks from disk infection:

1. *Type I* degenerated end plates are also hypointense on T1-weighted images and hyperintense on T2-weighted images and may enhance with gadolinium. However, no change should occur in the appearance of the unenhanced disk after uncomplicated discectomy. Comparison of preoperative and postoperative scans is thus important. Furthermore, the cortical margins should remain sharp after uncomplicated discectomy, whereas the margins are indistinct in infection.
2. *Type II* degenerated end plates have high signal intensity on T1-weighted images and high to slightly lower signal intensity on T2-weighted images. This high T1 signal may mask the low T1 signal found in disk space infection. In this case, too, it is important to look for abnormal disk signal, to compare preoperative and postoperative scans, and to evaluate cortical margins.
3. Infected disks and end plates usually enhance with gadolinium; uncommonly, however, the normal postoperative disk can enhance. Boden and colleagues⁷ observed that it is unlikely for normal postoperative patients to have all three abnormal findings (i.e., low disk/end-plate signal on T1-weighted images, high disk/end-plate signal on T2-weighted images, and disk/end-plate enhancement with gadolinium). This "triad" suggests disk infection in the symptomatic patient.

MRI using fat suppression has made the diagnosis of postoperative diskitis/osteomyelitis easier. Short tau inversion recovery (STIR) imaging shows disk and bone edema that may be difficult to visualize on T1-weighted and T2-weighted images because of bright, fatty marrow obscuring the edema (Fig. 22-39C).

Epidural Abscess

Epidural abscess is also hypointense on T1-weighted images and hyperintense on T2-weighted images and shows mass effect on the thecal sac. Because these changes may be masked by the similar signal of CSF, gadolinium should be given when epidural abscess is suspected (Fig. 22-39).⁷⁶

Cervical Spine

After the lumbar spine, the cervical spine is next most commonly affected by spondylosis and disk herniation.⁵⁷ The most frequently involved interspaces are C4-5, C5-6, and C6-7. This may be due to the greater degree of motion at these levels.²¹ Although many concepts of nondiskogenic and diskogenic degeneration (osteophyte formation, foraminal stenosis, spondylolisthesis, and disk herniation) are much the same as in the lumbar canal, a couple of important anatomic and clinical differences should be emphasized:

1. Because the cervical spinal cord carries neurons from

both the upper and lower extremities, symptoms referable to arms, legs, or both may occur.

2. Because the dimensions of even the normal cervical spinal canal are small relative to the lumbar, small spondylitic or disk changes may cause significant symptoms.

Anatomic Considerations

Although the basic anatomy of the cervical and lumbar vertebrae and diskovertebral junctions are similar, several important differences as they may relate to spondylosis warrant brief review.

Unlike the more rounded configuration of the lumbar sac, the cervical spinal canal is triangular. The cervical spinal cord is oval (Fig. 22-40). The canal decreases in size from C1 to C3 and is uniform from C3 to C7. The normal lower limit anteroposterior diameter of the canal is 16 mm at C1, 15 mm at C2, and 12 mm in the lower cervical spine.⁵²

The exiting cervical nerve roots travel in an inferior direction through the foramina at about 45 degrees with respect to the coronal plane (Fig. 22-41). This differs from the lumbar roots, which travel inferiorly but nearly parallel with the coronal plane. This makes sagittal imaging of the cervical nerve roots less optimal than in the lumbar spine.

The cervical nerve roots exit above (not below, as in the lumbar spine) the pedicle of its corresponding vertebral body. Because there are eight cervical roots but only seven vertebrae, the relationship changes at the C8 root, which passes above the T1 pedicle. The T1 root then passes under the T1 pedicle and the pattern is the same as in the lumbar spine the rest of the way down.

In addition to the body, laminae, pedicles, spinous, and transverse processes, the cervical vertebrae have uncinate processes, or joints of Luschka, paired bony ridges projecting superiorly from the posterolateral margins of the vertebral bodies. They fit into notches on the posterolateral surfaces of the inferior end plates of the vertebral bodies above. On axial images, they can be seen indenting the posterolateral disk margin as they bridge the vertebral bodies (Fig. 22-42; see Fig. 22-41). The uncinate processes contribute to the anterior walls of the neural foramina; if hypertrophied, they can cause foraminal stenosis. Whereas the lumbar facet joints are fairly sagittally oriented, the cervical facets are obliquely positioned, their surfaces lying halfway between a coronal and axial plane (see Figs. 22-41 and 22-42).

The vertebral arteries pass through the bony transverse foramina, located on the lateral aspects of vertebrae C1 to C6 (see Fig. 22-40). The arteries can rarely be compressed by foraminal spurs.

Imaging Techniques

At our institution, CT scans of the cervical spine for degenerative disease are usually done following myelography (see Figs. 22-40 and 22-42). Investigators have found that the increased sensitivity of CT myelography over standard CT in the cervical spine is even greater than in the

Figure 22-40. Cervical images. *A*, Cervical postmyelogram CT scan. Note the triangular configuration of the spinal canal (arrows) and oval shape of the spinal cord (white asterisk). The nerve root sheaths (black asterisk) can be seen exiting through the neural foramina. *B*, Axial cervical T1-weighted MR image. c, spinal canal; s, spinal cord. Arrows indicate nerve roots; arrowheads indicate vertebral arteries in the transverse foramina.

lumbar spine.¹² After myelography, 2-mm contiguous axial images through the levels of concern are obtained. Both bone and soft tissue windows are photographed. Unlike lumbar CT myelography, cervical CT myelography is done soon after the intrathecal injection because contrast mate-

rial in the cervical canal tends to flow away from the cervical canal more quickly and the injection volume is generally smaller than in the lumbar canal (Box 22-3).

As in the lumbar spine, numerous choices are available for MRI of the cervical spine. We obtain a set of fast spin-echo, T1-weighted and T2-weighted sagittal images of the entire cervical region (Fig. 22-43). These images should include the cerebellar tonsils down to the first thoracic level.

With the development of stronger x-y-z gradient coils,

Figure 22-41. Axial cervical gradient-echo MR image. The exiting nerve roots approach the neural foramina at a 45-degree angle. Both the anterior and posterior divisions can be seen (black arrows); they then join to form the dorsal root ganglia in the foramina (white arrows). Note hypointense uncovertebral joints of Luschka (asterisks) indenting the posterolateral disk (d) margins.

Figure 22-42. Cervical postmyelogram CT scan. The uncovertebral joints of Luschka are indenting the posterolateral disk (d) margins (arrows) (see Fig. 22-41). Note also the near-horizontal orientation of the facet joints (arrowheads) (see also Fig. 22-41).

Box 22-3. Routine CT of Cervical Degenerative Disease

- Axial contiguous images from C2 to T1
- Slice thickness = 2–3 mm, intersection gap = 2 mm
- Both wide and narrow window settings
- Intrathecal contrast preferable

matrices in the range of 300 to 600 can be obtained, greatly increasing image resolution. The stronger gradients also allow for shorter imaging times and larger fields of view (allowing inclusion of the upper thoracic spine in the cervical images—a request often made by referring physicians) with little or no decrease in image resolution. We also obtain a set of 2D gradient-echo as well as 3D (volume) gradient-echo axial images from the C3-4 interspace down to at least the C6-7 interspace. The T1-weighted images are used for evaluation of overall anatomy and marrow abnormalities. The gradient-echo images bring out the “myelographic effect,” enhancing contrast between bone-root-cord and CSF (see Fig. 22-41). We use both 2D and 3D gradient-echo axial views because we find that overall image quality tends to be better with 2D sequences, but the thinner slices obtained with 3D sequences often help to detect small lesions. We apply a magnetization transfer pulse to the 3D images to help darken the cord and roots, thus increasing the myelographic contrast effect.

Again, imaging sequences may vary widely among institutions. For instance, some centers routinely obtain T1-weighted axial views, whereas we do not, except in the postoperative cervical spine. All 2D images are 3 to 4 mm

Box 22-4. Example of Routine MRI of Cervical Degenerative Disease

1. Sagittal fast spin-echo, T1-weighted image to include cerebellar tonsils to T1 level
 - a. Field of view = 26–28 cm, thickness = 3–4 mm, intersection gap = 1 mm, matrix = 256×512
2. Sagittal fast spin-echo, T2-weighted image to include cerebellar tonsils to T1 level
 - a. Field of view = 26–28 cm, thickness = 3–4 mm, intersection gap = 1 mm, matrix = 384×512
3. Axial 2D gradient-echo sequence to cover at least C2-3 through C6-7 interspaces
 - a. Field of view = 20 cm, thickness = 3 mm, intersection gap = 1 mm, matrix = 384×512
4. Axial 3D gradient-echo sequence contiguous to cover at least C2-3 through C6-7
 - a. Field of view = 20 cm, reconstructed thickness = 2 mm, matrix = 512×512
 - b. Apply magnetization transfer pulse
5. If postoperative spine, substitute noncontrast T1-weighted, fast spin-echo axial views for one of the gradient-echo sequences
 - a. Field of view = 20 cm, thickness = 3 mm, intersection gap = 1 mm, matrix = 256×256

thick with a 1- to 1.5-mm gap (Box 22-4). Given the 45-degree angle of the exiting nerve roots, some authors advocate using sagittal oblique images (perpendicular to the foramina) rather than direct sagittal views for optimal foraminal imaging.⁵⁵ This, however, requires two separate sets of oblique images, one for each side, and is therefore more time-consuming. We occasionally make use of the

Figure 22-43. Sagittal fast spin-echo, T1-weighted (A) and T2-weighted (B) cervical MR images. The field of view should include cerebellar tonsils to at least the first thoracic level. A large field of view helps to include the upper thoracic spine.

sagittal oblique when there is obvious clinical radiculopathy without obvious MRI findings. The oblique images occasionally reveal small, but strategically located intraforaminal disk herniations.

Because the cervical spine is small and "crowded," volume averaging, patient motion, flow and pulsation artifacts, and small-structure (e.g., foraminal stenosis) evaluation are more problematic in the cervical than in the lumbar spine. More refined imaging techniques (e.g., volume imaging, fast spin-echo imaging, magnetization transfer, motion compensation) to alleviate these problems are evolving rapidly, and numerous new sequences and techniques emerge constantly.

Nondiskogenic Spinal Stenosis

Degenerative disease of the cervical spine is very common after age 40 and may, in fact, affect 70% of people

older than age 70.^{37, 43} In older individuals, *facet hypertrophy* and *osteophytosis* become more problematic than disk herniation; whereas osteophytes and facet disease worsen with age, disk material becomes harder, more immobile, and less likely to protrude.⁸ As in the lumbar spine, osteophytes can compress any portion of the neural canal and foramina (Fig. 22-44). Ligamentum flavum hypertrophy can contribute to spinal and foraminal stenosis (see Fig. 22-44). Unique to the cervical spine are the uncinate processes, or joints of Luschka, which contribute to the anterior wall of the neural foramina. Uncinate hypertrophy or osteophytosis, therefore, may lead to foraminal stenosis (Fig. 22-45).^{45, 58} Facet hypertrophy generally narrows the foramina (see Fig. 22-45).

CT is well suited for visualization of bone and facet disease. On MRI, osteophytes can be of high, intermediate, or low signal intensity on T1-weighted images, depending on their yellow marrow content.⁵⁴ Intermediate-signal and low-signal osteophytes may blend in with adjacent liga-

Figure 22-44. A, Sagittal gradient-echo MR image shows multiple osteophytes (*small arrows*) encroaching on the thecal sac. Ligamentous hypertrophy (*large arrows*) is also present posteriorly. B, Postmyelogram CT scan shows an osteophyte (*arrow*) flattening the right aspect of the canal and cord. C, Postmyelogram CT scan shows posterior element osteophytes (*arrows*).

Figure 22-45. Postmyelogram CT scan (A) and axial gradient-echo (B) MR image show hypertrophied uncovertebral joint (closed arrows) narrowing the right neural foramen. Right-sided facet hypertrophy (curved arrows) contributes to this narrowing. Note also osteophytes (open arrows).

ments and CSF in the cervical region, where volume averaging is already a problem.

As mentioned, we obtain gradient-echo images in the cervical region, which makes bone very dark regardless of marrow content. This stands out nicely against the myelographically bright CSF. One must beware, however, of the “blooming” effect, in which osteophyte size may be exaggerated on gradient-echo sequences owing to magnetic susceptibility. Thus, spinal stenosis secondary to osteophytes seen on gradient-echo sequences should be confirmed on T1-weighted images, whose magnetic susceptibility effects are not as prominent.

Posterolateral bone, ligament, and facet disease, which impinge on the nerve roots, can lead to upper extremity radiculopathy. Central disease that compresses the cervical cord can produce myelopathy as well,^{10, 28, 59} resulting in lower extremity symptoms, including spasticity, weakness, and gait disturbance.^{8, 28} Clinically, this syndrome must be differentiated from other forms of myelopathy, such as multiple sclerosis, spinal neoplasm, and various intrinsic spinal cord diseases. In addition, if large spurs compress the vertebral arteries, symptoms of vertebrobasilar insufficiency may occur.⁸

Although common in Japan, *ossification of the posterior longitudinal ligament* (OPLL) is a fairly rare cause of spinal stenosis in the United States. There is no known etiologic mechanism. The ossified posterior longitudinal ligament can impinge on the spinal canal, resulting in nerve root or spinal cord compression. This entity is well visualized on plain films as a vertical band of ossified tissue along the posterior margin of the vertebral bodies. On CT scans, the involved portion of the ligament is replaced by the high density of calcium. On MR images, the ossification is represented by low signal on short TR, long TR, and gradient-echo sequences (Fig. 22-46). However, fatty marrow within the ossification can yield areas of high signal intensity on T1.⁶¹

Diskogenic Spinal Stenosis

Early in the course of cervical spinal osteoarthritis, the most common cause of pain is direct nerve-root compression by a laterally herniated cervical disk, which ordinarily occurs without prior trauma. This results in neck and arm pain with paresthesias in a dermatomal distribution. Both sensory and motor abnormalities occur. Cervical disk herniations are most common in the second through fourth decades of life.⁸

These herniations are well seen on both CT myelography (Fig. 22-47) and MRI (Fig. 22-48) as extradural soft tissue masses contiguous with the parent disk and focally protruding posterolaterally into the canal and/or neural foramina. Central disk herniations are less common and can cause spinal cord compression, resulting in myelopathy as well as radiculopathy (Fig. 22-48E).⁸

Postoperative Cervical Spine

Postoperative Changes

Most decompressive procedures on the cervical spine are now performed via an anterior approach.^{15, 34, 65} With the *Smith-Robinson* technique, the disk and end-plate material are removed and are replaced with an osseous wedge from the iliac bone.⁶⁵ During the *Cloward* technique, the surgeon removes posterior and posterolateral osteophytes, drills a hole into the disk space and end plates, and reinserts a prefitted piece of bone.¹⁵ Strut grafts are used for cervical stabilization after multilevel decompressive surgery is performed. The grafted bone bridges the involved vertebral bodies.

Although these techniques are commonly used, many other approaches, both anterior and posterior, are available (Fig. 22-49). In the immediate diskectomy-fusion postoperative period, the signal intensity of the intervertebral bone

Figure 22-46. Ossified posterior longitudinal ligament. Axial noncontrast CT scan (A) and axial gradient-echo MR image (B) show the ossified ligament (arrows) impinging on the spinal canal.

Figure 22-47. Postmyelogram CT scans of cervical disk herniation. A, Lateral disk herniation flattens the left side of the spinal cord (arrow). Note also osteophytes. B, Slightly lateral disk herniation (arrow). C, Central disk herniation (black arrow). These are somewhat less common in the cervical spine. Bilateral uncovertebral hypertrophy (white arrows) are also seen.

Figure 22-48. MR images of cervical disk herniation. Sagittal fast spin-echo, T1-weighted (A) and axial gradient-echo (B) images show a small central disk herniation (arrows). In the cervical spine, herniations can be quite subtle. Sagittal fast spin-echo, T1-weighted (C) and T2-weighted (D) images of multiple disk herniations (arrows) in a single patient.

Illustration continued on following page

Figure 22-48 Continued

E-G, Axial gradient-echo images in a patient with multiple disk herniations. *E*, This centrally herniated disk severely narrows the canal at one level (arrow). *F*, This laterally herniated disk severely narrows the left foramen (arrow) at another level. *G*, Osteophytes, which are much darker than disk herniations on gradient-echo imaging, are present as well (arrow).

grafts on MRI may be quite variable, according to whether the marrow is cellular or fatty and whether the bone is cancellous or compact. Adjacent end plates can have normal signal or signal that reflects postoperative Disk and end-plate changes in the late postoperative period are even more variable, reflecting not only the composition of the bone graft but also, possibly, the amount of revascularization, postoperative stresses, and intraoperative trauma received by the end plate and graft.^{70, 73}

Strut grafts are easily seen as long wedges of bone bridging the anterior aspects of the vertebral bodies. On MR images, the signal of the bulk of the graft may be variable but low-signal cortex outlines the graft margins (see Fig. 22-49). Solid bony fusions without replacement of disk by graft are seen as continuous marrow signal with no definable interspace (Fig. 22-49C). One of the most common types of procedures seen today involves anterior discectomy, followed by interbody fusion with a piece of bone and placement of an anterior plate-screw device for maximum stability (Fig. 22-49D-G).

Complications

Complications of cervical spine decompression are similar to those in the lumbar region, including (1) bony stenosis, (2) disk herniation, (3) pseudomeningocele, and (4) infection. There are, however, some differences.

1. Bony stenosis may be caused not only by osteophyte formation but also by uncovertebral hypertrophy or by overgrowth of the fusion mass itself. These can produce spinal as well as foraminal stenosis. When one is looking at gradient-echo images of the cervical spine, the surgical material used may cause magnetic susceptibility "blooming" artifact and may mimic severe spinal stenosis when in fact no stenosis exists (see Fig. 22-49D-G). It is important, therefore to examine all images carefully, especially the T1-weighted and T2-weighted sequences. These sequences (especially FSE) tend not to exaggerate the degree of spinal stenosis. We substitute a set of T1-weighted axial images for one of the gradient-echo axial views to mitigate these artifacts in the postoperative cervical spine (see Fig. 22-49G).

Figure 22-49. Various types of cervical fusions.

E, Fast spin-echo, T2-weighted sequences produces artifact from the metal portion of the graft (arrows) but does not show significant spinal stenosis. *F*, Axial gradient-echo image. Artifact falsely suggests severe spinal stenosis. *c*, cord. *G*, Axial T1-weighted image shows the true, nonstenotic configuration of the canal. *B*, bone graft; *C*, cord; *P*, metal plate.

2. Because most or all of a disk is removed and replaced in a cervical discectomy and fusion, postoperative recurrent disk herniations tend not to occur unless residual disk material is inadvertently left behind. Graft extrusion, however, is an uncommon complication that can mimic a herniated disk at the operative level. Cervical disk herniations at nearby levels can occur from the altered stresses within the spine.⁷⁰
3. Cervical spine instability can be a significant problem in a patient's status after cervical laminectomy.⁶⁷ Both MRI and CT scans with sagittal or coronal reconstructions can demonstrate postoperative scoliotic, kyphotic,

and rotational deformities as well as malalignment. These scans can also be performed in flexion and extension to demonstrate abnormal motion. Unfortunately, no effective way of evaluating graft integrity by CT or MRI exists to date.

Thoracic Spine

Both disk herniation and spinal stenosis of the thoracic spine are less common than in the lumbar and cervical spine. The infrequency of thoracic spinal stenosis is proba-

Figure 22-50. Sagittal fast spin-echo, T1-weighted (A) and T2-weighted (B) thoracic MR images. The entire thoracic spine as well as the cervical spine is easily included in the field of view.

bly due to the large size of the thoracic canal relative to the cord.⁵¹ To produce compressive symptomatology, bony or ligamentous hypertrophy must be fairly large. The incidence of thoracic disk herniation is also less than in the remainder of the spine. This is presumably due to the limited mobility of the thoracic spine and because the weight-bearing axis does not intersect the posterior margins of the vertebral bodies.^{5, 66} Most patients with operated thoracic disks report an incidence of less than 2%, although autopsy series report an incidence of between 7% and 15%.² With the emergence of MRI, these herniations are being recognized with increased frequency.⁷⁴

Imaging Techniques

MRI demonstrates both thoracic canal stenosis and thoracic disk herniations quite well. MRI is also useful for

Box 22-5. Example of Routine MRI of Thoracic Degenerative Disease

1. Sagittal T1 to include entire thoracic spine
 - a. Field of view = 40 cm, slice thickness = 3–4 mm, intersection gap = 1 mm, matrix = 512 × 512
2. Sagittal fast spin-echo, T2-weighted image to include entire thoracic spine
 - a. Field of view = 40 cm, slice thickness = 3–4 mm, intersection gap = 1 mm, matrix = 512 × 512
3. Axial fast spin-echo, T1-weighted and T2-weighted images through areas of concern as needed

Figure 22-51. Normal postmyelogram thoracic CT scan. Note the round shape of the normal thoracic cord and canal.

excluding other causes of thoracic disease, such as tumor or infection. At our institution, we obtain T1-weighted sagittal sequences, followed by FSE T2-weighted sagittal sequences (Fig. 22-50). These images are then inspected, and axial images are obtained through the level of concern as needed (Box 22-5).

CT myelography complements MRI in evaluation of spinal stenosis caused by bony hypertrophy or ligamentous ossification owing to its superior ability to image calcium. Because of its length, covering the entire thoracic spine with CT using a reasonable number of slices is difficult. Therefore, if CT scanning is to be performed, it is probably best done after myelography or MRI to define the level of pathology (Fig. 22-51). CT images can then be obtained through the level of concern (Box 22-6). With modern, large field-of-view coils, MRI can be used to depict the entire thoracic spine in one shot (see Fig. 22-50), thus making MRI the preferred imaging modality for thoracic degenerative disease.

Nondiskogenic Spinal Stenosis

Acquired thoracic spinal stenosis can result from hypertrophy of the bony posterior elements.⁸⁴ Since the advent of CT scanning, hypertrophy or calcification of the posterior longitudinal ligament (Fig. 22-52) and degenerative ligamentum flavum hypertrophy are also being recognized with increased frequency in the thoracic spine.^{3, 50}

Figure 22-53. Sagittal (A) and axial (B) T1-weighted MR images of central disk herniation (*arrows*). C, Postmyelogram CT scan of slightly lateral disk herniation (*arrow*).

Diskogenic Spinal Stenosis

Most thoracic disk herniations occur in the lower thoracic spine. T11 and T12 are the most common locations. Unlike the case with the rest of the spine, most thoracic herniations are centrally, rather than laterally, located (Fig. 22-53). Multilevel thoracic herniation is rare. Most patients with thoracic disk herniations are between 30 and 50 years of age.⁶⁶

Nondegenerative Spinal Stenosis

Nondegenerative spinal stenosis has numerous causes, the most common of which is idiopathic congenital or

developmental narrowing of the spinal canal. This is probably due to inadequate development of the canal and foramina. Symptoms usually arise when degenerative changes of disks, facets, and ligaments are superimposed on an already small canal.²⁵

Box 22-7 summarizes the nondegenerative causes of spinal stenosis.

Extramedullary Spinal Tumors

Donna M. Plecha

Progress continues to be made in the evaluation of extramedullary spinal tumors. Magnetic resonance imaging (MRI) is usually the imaging modality of choice for evaluating the spine if there is clinical concern for tumor. Although MRI is not usually helpful in determining the specific diagnosis or for grading neoplasms, it is excellent for determining the extent of involvement as well as anatomic detail such as spinal cord compression, and it may help to limit the diagnostic possibilities. It has also facilitated the determination of whether a tumor is extradural, intradural/extramedullary, or intramedullary.

Extradural Tumors of the Spine

Extradural tumors of the spine are the most common of all spinal tumors. Most extradural tumors of the spine are metastatic lesions because the vertebral bodies are highly vascularized. The thoracic spine is most commonly involved. Spinal cord compression is seen in 5% of cancer patients with bone metastasis.⁴ Metastatic lesions in the epidural space usually result from direct extension of vertebral body metastasis. Otherwise, there can be epidural involvement from hematogenous spread through the epidural and paravertebral venous plexus.¹³

Most metastatic lesions of the spine originate from breast, lung, or prostate cancer.²⁴ The most common initial symptoms include local pain and radicular pain. With more advanced disease, motor dysfunction and/or sphincter dysfunction may occur. Therapies include surgery and radiation, or both,^{3, 4, 41} and preoperative transarterial embolization of the spinal metastasis. The latter is safe and effective; it can limit blood loss during surgery and aid in more complete tumor resection.³⁹ Outcome is related to the patient's condition at diagnosis, radiosensitivity of the tumor, and tumor biology.³¹ Early initiation of therapy is important to preserve motor function.⁴¹ Bach and colleagues⁴ found that 79% of patients who could walk at diagnosis were still ambulatory after treatment, but only 18% of nonambulatory patients were able to walk after therapy. Therefore, timely initiation of therapy is critical.

Spin-echo (SE) T1-weighted sequences are excellent for determining the extent of metastatic disease because of their high signal-to-noise ratio. Also, the high fat content of the bone marrow contributes to excellent contrast (Fig. 23-1). The metastatic lesions alter the usual fat content within the vertebral bodies, thereby causing a decrease in signal intensity on T1-weighted SE images. T2-weighted SE sequences are also helpful as abnormal bone marrow usually demonstrates increased signal intensity on T2-

weighted images. In addition, fat saturation techniques offer potential advantages for increasing the conspicuousness of bone marrow lesions. T2-weighted fat-saturated fast spin-echo (FSE) and short TI inversion recovery (STIR) sequences have also been used to increase lesion conspicuity.^{26, 32}

Abnormal bone marrow signal intensity on any imaging sequence is nonspecific and does not always mean that a patient has metastatic disease. Kim and colleagues attempted to differentiate between hematopoietic malignancies and metastasis.¹⁶ They assessed lymphoma, leukemia, and multiple myeloma lesions in an attempt to distinguish them from metastasis using the following criteria: pattern of involvement, signal change of the vertebral body, location of the paraspinal mass, cortical destruction, contour change, and compression fracture. Although the two categories overlapped, diffuse involvement was more commonly seen in hematopoietic malignancies than in metastasis, and cortical destruction was more commonly seen in metastasis than in hematopoietic malignancies. The other parameters examined failed to show any statistically significant difference between the two groups.¹⁶ The authors found that it was difficult to evaluate young patients because of persistent red marrow.

Patients with metastatic disease often present with compression fractures. When a patient does not have widespread metastatic disease, it is sometimes difficult to differentiate between pathologic and benign compression fractures of the spine, and various MRI sequences have been used in an attempt to differentiate between them. Baker and colleagues⁵ examined 53 patients with a total of 34 benign compression fractures and 27 pathologic fractures. The authors used a presaturation technique, suppressing either fat or water signal with a presaturation pulse, to obtain "fat" and "water" images. STIR and SE images were also used.

Most compression fractures more than 1 month old showed marrow signal isointense to that of the surrounding normal vertebral bodies. When the fracture was acute, however, the edema caused signal intensity changes similar to vertebral bodies involved with tumor. Only seven patients had acute benign fractures less than 1 month old. All showed high signal intensity on T2-weighted images and low signal intensity on T1-weighted SE images. In five of the patients, the water images and the T2-weighted images of the problematic vertebral bodies showed heterogeneous patterns. In the other two patients, the involved vertebral bodies showed diffusely homogeneous increased signal intensity throughout.

Another seven patients had pathologic compression fractures, all of which showed homogeneous diffuse decreased

Figure 23-1. A, Sagittal T1-weighted image of the thoracic spine demonstrating multiple areas of abnormal bone marrow signal intensity. This patient has diffuse metastatic disease. B, T1-weighted axial image shows a right-sided metastatic mass causing mass effect on the spinal cord and thecal sac.

signal intensity on the T1-weighted images and increased signal intensity on the T2-weighted, STIR, and water images. The fat images showed a complete absence of fatty marrow signal intensity. Therefore, the patterns of signal intensity changes between the two groups did overlap.

Because each group was composed of only seven patients, it is difficult to determine whether the findings are statistically significant. Another difference between the benign and malignant acute fractures was that the pathologic fractures tended to have convex outward anterior and posterior margins compared to the more sharply angulated borders of the acute benign fractures.

Baur and colleagues⁷ assessed MR diffusion-weighted imaging (DWI) for its ability to distinguish between malignant and benign causes of spinal compression fractures. When they studied DWI of bone marrow, they found that acute benign compression fractures either showed lower signal intensity than normal bone marrow or were isointense with normal bone marrow. They thought that this difference was caused by free extracellular water in the bone marrow edema and/or hemorrhage. When DWI is used, increased signal intensity is seen where diffusion of water is decreased or restricted, such as in vertebral bodies invaded by tumor cells. Baur and coworkers⁷ demonstrated that the pathologic fractures showed increased signal intensity within the bone marrow; this corresponded to a decrease in the apparent diffusion coefficient.

MR DWI does have drawbacks, however. For example, it has low spatial resolution and a low signal-to-noise ratio. In an editorial, Le Bihan²⁰ argued that it is more difficult to separate the effects of T1 and T2 from diffusion effects with the steady-state free precession (SSFP) diffusion se-

quence than with an SE-based diffusion sequence. SSFP diffusion-weighted imaging needs to be studied further to establish its usefulness in distinguishing pathologic from benign vertebral fractures.

Percutaneous vertebroplasty has been used in patients with compression fractures (Fig. 23-2). This procedure, developed in France, involves injection of polymethylmethacrylate cement into the collapsed vertebra. The stabilization and reinforcement provided by the cement can alleviate pain. Barr and colleagues⁶ performed percutaneous vertebroplasty in 47 patients (eight of whom had tumor involvement in the spine) for stabilization of the spine. Only 50% of the patients experienced significant pain relief. Possible complications of this procedure include cement extravasation and asymptomatic epidural venous filling.

Multiple Myeloma

As stated, multiple myeloma can appear similar to metastatic disease on spine images. Usually, compressive lesions involve the spine. When the disease is isolated to a single vertebral body, it is called a plasmacytoma. When multiple bones are involved, the term *multiple myeloma* is used. Multiple myeloma is more common in men and is usually seen in the sixth decade of life.

The tumor is composed of monoclonal B cells within the bone marrow. The lesions show decreased signal intensity on T1-weighted images and increased signal intensity on T2-weighted images (Fig. 23-3). A study examining

Figure 23-2. A, Axial CT image with needle in place through the pedicle of a metastatic vertebral body during percutaneous vertebroplasty. B, Axial CT image after injection of polymethylmethacrylate cement.

Figure 23-3. A, Axial CT image through the T11 vertebral body shows a destructive lesion with a soft tissue component, which proved to be multiple myeloma. B, Sagittal T1-weighted image through the lumbar spine shows compression and bone marrow replacement of the T11 vertebral body with associated spinal cord compression. There is also abnormal signal intensity in the surrounding vertebral bodies. C, T1-weighted axial image demonstrating significant spinal cord compression secondary to multiple myeloma mass involving T11. The abnormal signal intensity of the mass is isointense to muscle.

the MRI characteristics of multiple myeloma found that these lesions were better identified with T2-weighted images than with T1-weighted images in 65% of patients.²² Another study found that STIR and T2-weighted images were better than T1-weighted images for detecting lesions and that contrast enhancement did not increase lesion detection.³⁴

Various patterns of involvement of spinal multiple myeloma have been described. Focal lesions, diffuse involvement, and a heterogeneous pattern of tiny lesions on a normal marrow background were described in a study of 29 patients.²⁷ It was noted that diffuse and focal marrow patterns of involvement were associated with more abnormal serum hemoglobin levels and a higher percentage of marrow plasmacytosis. A similar study showed similar results: the diffuse pattern corresponded to patients with higher marrow plasmacytosis, higher cellularity, higher serum calcium, higher β_2 -microglobulin levels, and lower hemoglobin levels.²¹

Another classification scheme was presented in a study of 61 patients.¹⁹ The MRI patterns noted were described as diffuse, nodular, diffuse and nodular, and normal. More patients showing the normal and nodular MRI patterns of bone marrow signal intensity survived than patients showing the diffuse and the diffuse and nodular patterns.¹⁹

Even though contrast-enhanced MRI was not found to be helpful in the initial detection of lesions in patients with multiple myeloma, it may be helpful for following their responses to therapy. Patterns of complete response to treatment included resolution of the marrow abnormalities seen before treatment and of persistent abnormality with peripheral rim enhancement. Signs of partial response included conversion of a diffuse pattern of involvement to a variegated or focal pattern, and a decrease of the marrow involvement seen on MRI with persistent enhancement.²⁸ A similar study of 18 patients demonstrated patterns of response that included rim enhancement, no enhancement, and early enhancement.³⁵

Lymphoma

Lymphoma within the spine can present in several different ways. There can be extension from primary involvement in adjacent paravertebral lymph nodes into the neuroforamen and spinal canal. Primary involvement can also occur within the highly vascular vertebral body, and it commonly extends into the epidural space, causing mass effect on the spinal cord and exiting nerve roots. Lymphoma can also arise in the epidural space along the leptomeninges and, rarely, in the intramedullary space, as is seen in 0.1% to 6.5% of patients with non-Hodgkin's lymphoma (Figs. 23-4 and 23-5).³⁷

Marrow involvement occurs in 4% to 14% of patients with Hodgkin's lymphoma, and the percentage is much higher in patients with non-Hodgkin's lymphoma.²⁹ MRI is the imaging modality of choice because it is sensitive in picking up marrow involvement and in detecting mass effect on the spinal cord and spread into the epidural space and paraspinal soft tissue. Mouloupoulos and colleagues describe a "wrap-around sign": tumor envelops the cortex

of vertebral bodies without altering the shape of these vertebral bodies. This sign was found in patients with lymphoma but not in those with metastatic disease or with multiple myeloma.²⁹

Primary Tumors of the Spine

Other extradural tumors include primary tumors of the spine, which occur much less frequently than does metastatic spinal disease. However, when a patient presents with a solitary lesion, a primary tumor of the spine should be considered. Both benign and malignant tumors can be seen in the spine. Patients usually present with nonspecific back pain.

Osteoid Osteoma

The lumbar spine is the most common site of osteoid osteomas, followed by the cervical, thoracic, and sacral spine.³⁰ Patients present with the classic symptoms of painful scoliosis, focal or radicular pain, gait disturbance, and muscle atrophy. The pain is worse at night, and salicylates usually help.³⁰ Vertebral posterior elements are usually involved.

Plain films reveal a round to oval area of lucency with surrounding sclerosis. Associated scoliosis may be found, with the lesion located at the concave apex of the curve. CT, the study of choice for evaluating osteoid osteoma,¹¹ reveals an area of low attenuation with surrounding sclerosis (Fig. 23-6) and sometimes a central calcification. MRI usually shows a nidus reflecting low to intermediate signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted images. Any associated sclerosis or calcification shows low signal intensity on all pulse sequences.³⁰

Osteoblastoma

Osteoblastoma is another benign tumor of the spine; it has no predilection for any particular location in the spine.¹⁷ Patients usually present with dull pain, paresthesias, paraparesis, and paraplegia. Scoliosis can be associated with osteoblastoma, although less frequently than with osteoid osteomas, and it may be convex toward the side of the lesion.³⁰ Most commonly, osteoblastomas are expansile with small calcifications and a sclerotic rim.¹⁸

The second most frequent radiographic appearance of osteoblastoma is that of a central radiolucent area with surrounding sclerosis that can have central calcification. This is similar in appearance to osteoid osteoma, yet the clinical presentation and curve of the scoliosis may help to differentiate between the two. Also, osteoblastomas are usually bigger and they more commonly extend into the vertebral body.

A third possible radiographic appearance of osteoblastoma is that of more aggressive bone destruction, with expansion and extension into adjacent soft tissues.³⁰ CT commonly shows expansile lesions with associated sclerosis; these lesions may also have a chondroid matrix. MR imaging is usually nonspecific yet it is helpful in determining mass effect on the adjacent spinal cord and thecal sac.

Figure 23-4. A, Sagittal MRI fast spin-echo T2-weighted image through the lumbar spine. A mass is seen posterior to the L4 vertebral body. The mass was biopsied and proved to be lymphoma. B, MRI sagittal spin-echo T1-weighted image through the lumbar spine following the intravenous administration of Gadoteridol. The mass enhances within the spinal canal. C, Axial T1-weighted image through the mass, which is extradural in location, causing mass effect on the adjacent thecal sac. D, Axial T1-weighted image through the mass, after the intravenous administration of Gadoteridol.

Figure 23-5. A, T1-weighted sagittal MRI image through the lumbar spine showing a large mass anterior to the spine from T11 to L4. There is destruction and replacement of the T11 vertebral body. B, T1-weighted sagittal image through the thoracic spine showing a large mass anterior to the mid and lower thoracic vertebral bodies, which turned out to be lymphoma. C, T1-weighted axial image demonstrating an extradural mass that is causing mass effect on the thecal sac on the right. D, T1-weighted axial image showing lymphoma surrounding the vertebral body and extending into the epidural space that surrounds the thecal sac.

Figure 23-6. Axial CT image showing a lucency of the lamina of T1 with surrounding sclerosis, which proved to be an osteoid osteoma.

Signal intensity is usually low to intermediate on T1-weighted and intermediate to high on T2-weighted images (Figs. 23-7 and 23-8).^{8, 17}

Giant Cell Tumors

Giant cell tumors (GCT) in the spine usually involve the sacrum, followed by the thoracic, cervical, and lumbar areas.³⁰ Pain is the most common presenting symptom; however, pain can be accompanied by neurologic deficits.³⁸ GCT usually presents as a large mass with bone destruction and bony expansion. When the sacrum is involved, the sacroiliac joint can be crossed. Within the spine, vertebral bodies are most commonly involved, although giant cell tumors can cross disk spaces and extend into the posterior elements, and they can be associated with vertebral collapse.³⁰

CT reveals a soft tissue attenuation mass, which may have a rim of sclerosis (Fig. 23-9). If hemorrhage is involved, however, a mixed attenuation mass, or possibly fluid-fluid levels, may be seen.

MRI usually shows a mass with mixed signal intensity.^{25, 30} Fluid-fluid levels of various signal intensities may be seen if hemorrhage is present. The signal intensity depends on the age and state of the blood: it may be high on both T1-weighted and T2-weighted images if blood is present. In the absence of hemorrhage, GCTs may have low to intermediate signal intensity on both T1-weighted and T2-weighted images; this may help to differentiate them from other tumors, which usually have increased signal intensity on T2-weighted images.³⁰

Complete resection is the treatment of choice for GCT, yet it is not always possible. Adjuvant radiotherapy is also used. It has been argued that radiation therapy should be used for patients with incomplete excision or for those with local recurrence.^{15, 38}

Aneurysmal Bone Cysts

Aneurysmal bone cysts are seen most commonly in the thoracic spine, followed by the lumbar and cervical spine. Symptoms, including pain and neurologic deficits, are usually associated with mass effect on the spinal cord.

Radiographs, CT, and MRI demonstrate an expansile lesion centered in the posterior elements that commonly extends into the vertebral bodies. This lesion is usually lytic as well as expansive, with eggshell-like peripheral calcification (Fig. 23-10). ABCs can cross disk spaces and extend into adjacent structures. Both CT and MRI can evaluate for fluid-fluid levels. MRI is, however, better at showing both the extent of the mass and the mass effect on the spinal cord and nerve roots. A soft tissue rim is often seen on CT. It appears as a rim of decreased signal intensity on all MRI sequences. This rim is a thickened periosteal membrane, which, together with septations, can enhance with gadolinium.

Complete resection is the treatment of choice, but it is not always possible because of tumor location and size. Radiation and embolotherapy have also been used as treatment.³⁰

Osteochondromas

Osteochondromas of the spine are uncommon. They usually occur within the cervical spine, especially at C2, and like most benign spinal lesions they usually occur in the posterior elements. CT imaging with thin slices is the modality of choice to evaluate osteochondromas. Continuity of the cortex and the marrow between the lesion and the vertebra is visible on CT (Fig. 23-11).³⁰ MRI can also be helpful in identifying mass effect on the spinal canal. Central yellow bone marrow shows high signal intensity on T1-weighted images because of its fat content, and the corresponding signal intensity on T2-weighted images is intermediate (Fig. 23-12).³⁰ Surgical resection is the treatment of choice.

Chordoma

Chordoma is an uncommon malignant tumor of the spine arising from a remnant of the notochord. It usually occurs at the sacrococcygeal region or at the skull base. Because it is a slow-growing tumor, chordoma usually presents as a large destructive lesion with an associated large soft tissue mass. Calcifications are commonly seen within the mass on radiographs and CT, and they usually occur peripherally. Attenuation in the center of the mass is low, and it may be higher peripherally.^{30, 36}

Coronal CT images are optimal for evaluating foramen and sacroiliac joint involvement. Advances in multidetector CT and in three-dimensional reconstructive capabilities may be helpful in evaluating the extent of disease. For determining the extent of disease in surrounding soft tissue, however, MRI is superior.³⁵ On T1-weighted images, chordoma usually shows low to intermediate signal intensity, and it shows high signal intensity on T2-weighted images because of its high water content (Fig. 23-13).³⁰

Complete excision of the chordoma is necessary because of its poor sensitivity to radiotherapy and chemotherapy, but complete resection is not always possible. Preoperative MRI may help to determine the amount of involvement in the adjacent gluteal muscles; this may be important when

Figure 23-7. A, Sagittal CT reconstructed image demonstrates a lytic lesion of the L3 vertebral body. This lesion proved to be an osteoblastoma. B, Axial CT postmyelogram image in the same patient, showing an expansile lesion of L3 involving the pedicle, vertebral body, and lamina of L3. There is also associated mass effect on the adjacent thecal sac. C, T2-weighted sagittal image demonstrating the osteoblastoma with increased signal intensity involving the L3 vertebra. D, T1-weighted axial image demonstrating the mass, which is isointense to muscle. The extension of the osteoblastoma into the canal is clearly demonstrated; the image shows the mass effect on the thecal sac.

Figure 23-8. A, Axial CT image through C7 demonstrating an expansile osteoblastoma of the C7 facet. B, Axial CT image after myelogram through C7 showing the mass involving the vertebral artery foramen on the left. C, T1-weighted sagittal image after injection of contrast material with the enhancing mass involving the left C7 facet. D, T1-weighted axial image through the osteoblastoma involving the C7 facet and lamina.

Figure 23-9. A, Frontal view of the lumbosacral junction showing giant cell tumor causing bone destruction of the left proximal sacrum and mass effect on the thecal sac, pushing it to the left. B, Axial CT image after myelogram, demonstrating a destructive soft tissue mass involving the posterior elements of the sacrum and causing mass effect on the thecal sac. C, T1-weighted sagittal image of the lumbar spine clearly demonstrates the giant cell tumor involving the posterior aspect of the sacrum. The mass has mixed signal intensity. Evidence of hemorrhage or fluid-fluid levels is not seen. D, T2-weighted sagittal image of the same giant cell tumor, demonstrating mixed signal intensity. Again, evidence of fluid-fluid levels is not seen. E, T1-weighted axial image of giant cell tumor of the sacrum demonstrating signal intensity that is mixed but higher than that of muscle.

Figure 23-10. A, Axial CT image demonstrating an expansile aneurysmal bone cyst (ABC) of the L5 vertebral body with some rimlike calcification. The extension of the mass into the spinal canal is not well delineated. B, T1-weighted sagittal image through the lumbar spine, demonstrating the ABC that involves the L5 vertebral body. The mass is mixed in signal intensity and extends into the spinal canal. C, T2-weighted sagittal image of the lumbar spine. The ABC has increased signal intensity, with areas of lower signal intensity within it. D, T1-weighted axial image through the L5 vertebral body after administration of contrast material. An enhancing, expansile ABC with pockets of nonenhancing fluid signal intensity extends into the spinal canal and posterior lateral soft tissues. The septations are enhanced, as stated in the text.

Figure 23-11. Axial CT image through an osteochondroma involving the spinous process and lamina of a vertebral body. This image demonstrates continuity of the cortex and marrow between the lesion and the vertebra.

Figure 23-12. A, Axial CT image demonstrating an osteochondroma that involves the posterior elements of the L1 vertebral body. This mass is not in the typical C2 location, and it is larger than usually seen. There is no definite continuity of cortex and marrow between the mass and L1. B, Axial CT image of L1, showing the same mass with scalloping of the right aspect of the spinous process and calcification within the mass. C, T1-weighted sagittal image to the right of midline. The osteochondroma is mixed in signal intensity. D, T2-weighted image of the lumbar spine shows the same mass having mixed signal intensity. This is a nonspecific appearance. E, T1-weighted axial image of the lumbar spine showing that the mass has mixed signal intensity and does not involve the spinal canal.

Figure 23-13. A, Plain film AP view of the sacrum. There is destruction of the inferior and left aspect of the sacrum. B, Lateral plain film of the sacrum demonstrating destruction of the inferior sacrum. C, Axial CT image of the sacrum. The soft tissue mass that is destroying the sacrum has proved to be a chordoma. This mass is in the usual sacrococcygeal region of the spine. D, T1-weighted sagittal image (with contrast enhancement) of the sacrum nicely demonstrating the extent of the soft tissue tumor, which exhibits mild enhancement. The mass is causing anterior displacement of the rectum. E, T1-weighted axial image of the sacrum demonstrating the chordoma and its effects on the surrounding tissues.

chordoma infiltrating the gluteal muscles may account for local recurrences.⁴⁶

Chondrosarcoma

Chondrosarcoma is most commonly seen in the thoracic spine, but it is also found within the posterior elements or the vertebral body. Patients usually have a good prognosis, because spinal chondrosarcoma is usually low grade.³⁰

CT is a sensitive modality for revealing the chondroid matrix characteristic of chondrosarcomas, the bone destruction, and the soft tissue component.⁴⁰ On CT, the soft tissue component can have decreased attenuation because its water content is higher than that of muscle.

MRI is helpful for evaluating any associated mass effect on the spinal cord and/or extension across disk spaces, which is seen in 35% of cases.^{30, 40} Because of the water content of this tumor, signal intensity within the soft tissue component is usually decreased on T1-weighted images and increased on T2-weighted images. The matrix shows decreased signal intensity on all imaging sequences.³⁰

Osteosarcoma

Osteosarcoma in the spine is rare; it is most commonly seen in the lumbosacral region and usually involves the vertebral body eccentrically. On plain films, osteosarcoma presents with a dense matrix; an ivory vertebral body can be seen. MRI is helpful in determining the extent of the soft tissue component and its effect on surrounding structures. If the matrix exhibits dense mineralization, it may appear to have decreased signal intensity on all MRI sequences. Patients with primary osteosarcoma of the spine have a very poor prognosis, with death usually ensuing within 2 years of the diagnosis.³⁰

Ewing's Sarcoma and Permeative Neuroectodermal Tumor

Ewing's sarcoma and permeative neuroectodermal tumor (PNET) are radiographically very similar and are usually seen within the sacrococcygeal region. Presenting symptoms include pain and often bowel and bladder dysfunction. Metastatic foci are more common, yet primary lesions are also seen. These tumors usually occur in patients between 10 and 30 years of age.³⁰ The lesion is usually centered in the vertebral body, and a soft tissue component is commonly present.

MRI is the modality of choice to determine both tumor extent and involvement of surrounding tissue. The appearance of the tumor on MRI, however, is nonspecific. Signal intensity is intermediate on T1-weighted images and intermediate to high on T2-weighted images.^{2, 14} Immunohistochemical studies are used to distinguish between PNET and Ewing's sarcoma.

Chemotherapy and radiation are the treatments of choice for both entities.³⁰

Intradural Extramedullary Tumors

Nerve Sheath Tumors

Nerve sheath tumors make up the majority of extramedullary tumors within the dural space. Patients commonly

present with radicular pain, possible gait disturbance, and sphincter dysfunction. The pain experienced results from the fact that the tumors usually arise on the dorsal sensory nerve root. Neurofibromas and schwannomas are both derived from Schwann cells; however, neurofibromas also have collagen and fibroblasts.⁹

Patients with neurofibromatosis type 1 (NF-1) usually have intraforaminal nerve sheath tumors extending into the spinal canal in a dumbbell-shaped configuration. Only about 1.6% of patients with NF-1 have symptomatic spinal tumors.⁴⁴ Patients with NF-2 usually have intraspinal intradural tumors, and 30% to 40% of these patients have neurologic deficits and symptoms.²³

Plain films, which are nonspecific, may show enlargement of the neuroforamen (Fig. 23-14). MRI is the study of choice for evaluation of these tumors associated with the spine. On T1-weighted images, nerve sheath tumors are typically isointense to muscle. Increased signal intensity on T2-weighted images is typical for nerve sheath tumors whether using conventional SE or FSE imaging.⁴³ Postgadolinium imaging is commonly used to increase conspicuity of lesions. Nerve sheath tumors commonly enhance brightly, thereby increasing detection (Figs. 23-15 and 23-16). Fat-saturation techniques following administration of contrast material are also helpful for lesion detection.¹²

Total resection of nerve sheath tumors is needed to prevent recurrence. Neurofibromas have nerve fibers passing through them and are therefore difficult to remove completely. Schwannomas are usually eccentric in location, making total resection easier.

Paragangliomas

Extra-adrenal paragangliomas are rare, originating from cells of neural crest origin. Usually these tumors are located at the glomus jugulare or near or within the carotid body. Spinal paragangliomas are rare and can be seen in the intradural, extramedullary compartment, usually in the lumbar spine in the area of the cauda equina.¹ Rarely, they are also seen in the cervical and thoracic spine.

Paragangliomas of the spine are predominantly of the sympathetic type. Patients usually present with symptoms related to spinal cord or nerve root compression. MRI findings, which are nonspecific, reveal an enhancing lobulated or ellipsoid mass that is encapsulated and usually found in the intradural extramedullary space. Paragangliomas are usually isointense to the spinal cord on T1-weighted imaging and nonhomogeneous on T2-weighted imaging. Generally, paragangliomas are slow growing and benign.⁴²

Intradural Extramedullary Metastases

Various types of intradural extramedullary metastases occur. Drop metastases originate from central nervous system primary neoplasms, such as cerebral glioblastoma, posterior fossa medulloblastoma, anaplastic astrocytoma, and ependymoma. These are seeded through the cerebrospinal fluid (CSF) from the head. They are most commonly seen in the lumbar location in the area of the conus medullaris or the cauda equina.

Figure 23-14. A, Lateral plain film of the cervical spine, demonstrating enlargement of a neuroforamen. B, Axial CT image through C2-C3, after myelography, showing an extra-axial mass that is causing mass effect on the spinal cord on the left and extending into the neuroforamen on the left. C, Gross specimen photograph of a smooth, bilobed schwannoma.

Nonvisceral neoplasms with CSF seeding include melanoma, lymphoma, and leukemia.⁴⁷ Systemic malignancies, such as breast and lung cancer, metastasize to the subarachnoid space. When these patients are diagnosed with intradural extramedullary spinal canal metastases, they usually have widespread disease and a very poor prognosis.¹⁰ Most of the metastatic lesions are found on the conus medullaris and the cauda equina.

Whatever their source, the intradural extramedullary metastatic lesions are usually best seen on postcontrast, T1-weighted MR images of the spine. The lesions are not as well seen on either precontrast T1-weighted images or T2-weighted images; however, these sequences are helpful in evaluating for spinal bone metastasis and spinal cord compression. Therefore, a combination of precontrast and postcontrast images is used to evaluate the spine in patients with suspected intradural extramedullary metastatic dis-

ease. The metastatic lesions are usually seen as nodular enhancing lesions on the conus medullaris and the cauda equina, yet they can occur anywhere along the intradural space of the spinal canal. Abnormally thin extramedullary areas of enhancement may also indicate metastatic disease.¹⁰

An intraspinal meningioma can present as an intradural extramedullary mass. As in the head, this mass is isointense to the cord on MRI T1-weighted and T2-weighted images, and it homogeneously enhances after the administration of contrast medium. Enhancement of the adjacent meninges is known as the dural tail sign. Quekel and Versteeg³³ argue that to evaluate spinal meningiomas for the dural tail sign, sagittal, axial, and coronal planes should all be obtained following the administration of gadolinium. The dural tail sign is very suggestive of meningioma.

Weil and coworkers⁴⁵ reported on a patient who had

Figure 23-15. A, T1-weighted post-contrast-enhanced sagittal image of the cervical spine, demonstrating an enhancing extra-axial mass posterior to C2-C3 in a patient with known neurofibromatosis type 1. B, T1-weighted sagittal post-contrast-enhanced image through the thoracic spine, with enhancing neurofibromas in the lower thoracic spine. C, T1-weighted axial image showing extra-axial enhancing neurofibromas.

Figure 23-16. A, T1-weighted off-center sagittal image of the cervical spine showing multiple intradural extra-axial neurofibromas. This patient has known neurofibromatosis 1. B, T1-weighted coronal image of the cervical spine clearly shows multiple extramedullary tumors of the cervical spine. C, T1-weighted post-contrast-enhanced axial image through the C1–C2 level, demonstrating bilateral enhancing extramedullary neurofibromas in a patient with known neurofibromatosis type 1.

concurrent intradural and extradural meningiomas in the cervical spine. They recommend that when an epidural meningioma is found on MRI, special attention should be paid to the intradural space to find the high incidence of a concurrent meningioma.

Summary

Extramedullary tumors of the spine are usually best imaged with MRI, although CT can sometimes be helpful.

Although the diagnosis is not always apparent, the radiologist can provide vital pretreatment information about the extent of disease and its effects on the spinal cord and nerve roots.

The Spinal Cord

Jeffrey L. Sunshine, Scott Kolodny

Classically, evaluation of lesions within the spinal neural axis has been made on the basis of anatomic location. Lesions can be divided into *extradural*, *intradural-extra-medullary*, and *intramedullary*. Intramedullary lesions of the spinal cord, in turn, can be subdivided according to their etiology into (1) ischemic disease; (2) vascular malformations; (3) neoplastic processes; and (4) infectious, inflammatory, and demyelinating diseases. After a brief review of spinal cord anatomy, this chapter focuses on the intramedullary lesions of the spinal cord and their appearances on magnetic resonance imaging (MRI) and, to a lesser extent, on computed tomography (CT) scans.

Anatomy

The spinal cord represents a caudal extension of the medulla oblongata; it terminates in the conus medullaris, typically at or just below the thoracolumbar junction in adults. The cord is slightly flattened along its anterior and posterior surfaces and is enlarged in two regions. The cord widens first for the brachial plexus at C3 to T2, then for the lumbar plexus at T9 to T12. The filum terminale represents extension from the conus to the coccyx, and the cauda equina refers to the extension of spinal nerve roots caudally from the conus within the lumbar subarachnoid space.

The three-layered meningeal covering of the central nervous system (CNS) is contiguous with the spinal cord, and all lie within the bony spinal canal. The innermost layer, the pia mater, is adherent to the surface of the cord and extends from the lateral surface of the cord to a dural arachnoid membrane, forming the dentate ligaments. The arachnoid membrane remains closely adherent to the outer layer, the dura mater, allowing for a potential subdural space between the two layers. The subarachnoid space remains filled with cerebrospinal fluid (CSF) and is contiguous with the intracranial subarachnoid space. The dura extends to the S2 level, forming the dural (thecal) sac, which is surrounded externally by epidural fat to fill the remainder of the volume of the spinal canal.

The gray matter of the spinal cord is located internally, in contradistinction to the gray matter of the brain, and is surrounded by white matter tracts; the proportion of gray matter increases in the cervical and lumbar regions. Both dorsal (sensory) and ventral (motor) roots arise along the entire length of the cord and these unite to form a total of 31 paired spinal nerves. There are 8 cervical, 12 thoracic, 5 lumbar, and 5 sacral roots.

The arterial supply to the spinal cord, although variable, can be divided into three major regions.⁷⁴ Branches of the intracranial vertebral artery, cervical vertebral arteries, and cervical trunks produce radicular arteries that form the

predominant blood supply to the cervicothoracic region, generally ending after the first several thoracic vertebral segments.

A single radicular artery, usually located at approximately the T7 level, supplies the midthoracic cord. This represents the smallest territorial division and typically extends from T4 through T8.

The artery of Adamkiewicz, which arises from a low thoracic or upper lumbar artery, supplies the final thoracolumbar region. This important artery usually arises from an intercostal branch in the region of T9 to T12. In a few people, it may arise from a branch at a higher level but then the conus medullaris can be additionally supplied from a lower and smaller radicular artery. Least often, the artery of Adamkiewicz arises from the upper lumbar arteries.

At the levels of the spinal cord, radicular branches enter the spinal canal through the neural foramina and lead to the anterior as well as to the paired posterior spinal arteries on the cord surface. These spinal arteries in turn generate a rich anastomotic arcade, with the anterior artery supplying the central gray matter and the posterior arteries feeding the dorsal columns and posterior peripheral white matter. Modern MRI machines and the newer gradient sequences allow excellent anatomic depiction of the arteries and veins of the spinal cord without the need to rely solely on catheter-based conventional angiograms.¹¹

Ischemia

Spinal cord ischemia can arise and lead to infarction for a variety of reasons, including trauma to or dissection of the arterial supply, atherosclerotic and embolic disease, hypotension (e.g., cardiac arrest), complications of thoracoabdominal surgery or spinal angiography, vasculitis, hypercoagulation diseases, and spontaneous idiopathic incidence. More rarely, cord ischemia and infarcts arise secondary to vascular malformations^{102,108} or to hypercoagulation diseases as in patients harboring antiphospholipid antibodies.⁴⁷ Spinal cord infarction can be iatrogenic, resulting from neurosurgical procedures performed with the patient in a sitting position⁹⁰ or as a result of wayward migration of embolic materials during endovascular interventions.⁷³ In addition to dissection of direct arterial supply to the cord, dissection or high-grade stenoses involving larger proximal vessels, such as the vertebral artery, have also caused cord infarction.^{4,115} In patients who have undergone trauma, the presence of intramedullary hemorrhage (Fig. 24-1) portends less chance of recovering motor activation and a good functional outcome.^{35,36}

Spinal cord ischemia has been described in four progres-

Figure 24-1. Spinal cord trauma with intramedullary hemorrhage. *A*, Axial CT section reveals the comminuted fracture of the vertebra and posterior elements with compression of the spinal canal. *B*, Sagittal CT reconstruction shows the anterior fracture of C5 and the posterior displacement of bone into the spinal canal. *C*, T1-weighted sagittal MR demonstrates the abnormal hypointense marrow signal in C5 from edema as well as the mild loss of height and again the posterior extension. No definite cord abnormality is seen. *D*, This axial FLASH (fast low-angle shot) T2-weighted section reveals two foci of abnormal hypointense regions within the cord from acute blood products.

sive patterns, best seen on T2-weighted axial MR images. The most descriptive and smallest insult produces hyperintensity limited to the paired anterior horns of the central gray matter in a pattern that has been descriptively labeled "owl's eyes."⁷⁴ Next, the paired posterior horns of the gray matter are involved in a pattern reminiscent of a butterfly

(Fig. 24-2). When the insult becomes more severe, the damage extends laterally to involve the corticospinal tracts. Finally, in the worst situations, the entire area of the cord can be homogeneously affected (Fig. 24-3). Insults that cause a change of signal intensity limited to the anterior horns most often have a better functional outcome, and

Figure 24-2. Cord infarction. A, T1-weighted sagittal MR image shows no definite intramedullary abnormality. B, T2-weighted sagittal MR image reveals marked focal hyperintensity along the central and posterior cord centered at C5. C, A gradient-echo, FLASH (fast low-angle shot), T2-weighted axial section demonstrates the butterfly pattern of cord infarction involving the bilateral anterior and posterior horns of the gray matter.

indeed embolic events to spinal arteries arising during catheter angiography have been reported to resolve spontaneously.³⁷

T1-weighted images best demonstrate associated swelling, particularly the associated enlargement of the cord.⁴⁷ Gadolinium-enhanced T1-weighted images show disruption of the blood-brain barrier in the late acute and subacute phases of infarction. This disruption tends to involve the peripheral margins of the central gray matter, whereas in anterior cord syndrome the ventral margins tend to be involved more than the peripheral, probably as a result of the posterior collateral supply.^{31,39} MRI, especially T2-weighted images, demonstrates associated abnormalities of the aorta and of adjacent vertebral bodies.^{34,131}

Vascular Malformations

Vascular malformations of and around the spinal cord have been variously classified as (1) dural arteriovenous

fistulas (AVFs), (2) perimedullary intradural or cord AVFs, (3) cavernous angiomas, and (4) spinal cord arteriovenous malformations (AVMs). Diagnosis of these malformations has been improved tremendously with the application of MRI techniques that enable the reliable demonstration of the primary vascular lesion and the secondary cord edema and myelopathy. Until very recently, diagnosis required confirmation by demonstration of the primary vasculopathy with conventional spinal angiograms, but the advent of contrast-enhanced MR angiography has allowed direct non-invasive demonstration of the lesions.^{5, 9, 10, 71, 72}

Spinal Cord Arteriovenous Malformations

Cord AVMs are congenital in origin and are composed of the typical nidus of abnormal vessels arising from arterial feeders that then lead directly to hypertensive "arterialized" venous drainage. Those with a typically compact, wholly intramedullary nidus have been termed *glomus*

Figure 24-3. Cord infarction. A, T1-weighted sagittal MR image shows cord expansion beginning at C3 and extending to C7. B, The T2-weighted sagittal MR image demonstrates the expansion as well as increased signal centrally at the same levels. C–E, Sequentially lower sections through the infarct show the normal cord (C); the widened cord (D), and the homogeneous hyperintensity of the central gray matter (E) on these FLASH, T2-weighted axial slices.

Figure 24-4. Intramedullary glomus arteriovenous malformation. A, T1-weighted sagittal MR image shows conus expansion around a central hypointensity that demonstrates heterogeneous signal. B, T2-weighted sagittal MR image demonstrates a greater heterogeneity and the more inferior extension of an enlarged curvilinear flow void probably representing a dilated draining vein. C, Angiographic image reveals the serpentine arterial input that enters the nidus from above and the dilated curvilinear draining vein below.

AVMs (Fig. 24-4), and those with a looser configuration that often extends into the extramedullary spaces have been labeled *juvenile-type AVMs*.² In rare instances, these malformations occur in conjunction with vertebral angiomatosis and skin nevi, all at the same metameric level; this is called the *Cobb syndrome*.⁸⁰

AVMs present a risk of hemorrhage and ensuing complications as well as effects of venous hypertension, which may include spinal cord edema, ischemia, or infarct. Indeed, this is the only subset of vascular malformations that show associated spinal artery aneurysm formation, most likely the result of long-standing high flow. When such aneurysms occur, they frequently hemorrhage.⁶

MRI can often be used to detect spinal AVMs when the effects of high flow, signal changes about the nidus, hemorrhage, and edema are readily apparent.⁶¹ In addition, the telltale curvilinear filling defects can be seen on CT

myelography.⁶⁰ Spinal AVMs that occur within the cord substance can be complicated by associated infarct that appears bright on T2-weighted images and enhances with gadolinium.¹⁰⁸ If spinal AVMs spontaneously thrombose (*Foix-Alajouanine syndrome*), an associated cord ischemia can occur, leading to cord infarct.¹⁰² Even greater sensitivity for the lesions, and in particular for the shunt, is gained through application of dynamic MRI using a T2-weighted sequence and tracking of a gadolinium bolus.¹²³

Spinal AVFs are the more common spinal cord vascular malformations; they are subdivided into malformations involving only the dural branches of a radicular artery (*dural AVFs*) and those arising directly from the spinal arteries (*intradural AVFs*). Dural AVFs are probably acquired, whereas intradural AVFs are thought to be congenital. The larger congenital lesions often present in childhood with hemorrhage of focal neurologic deficits.¹⁰⁴

Dural Arteriovenous Fistulas

Dural AVFs, whose point of shunt is within the dural surface, comprise the majority of all spinal vascular malformations.⁹³ The resultant venous engorgement can produce venous hypertensive changes in the spinal cord, often in the midthoracic to upper lumbar region, that in turn induce cord myelopathy. The myelopathic changes, both clinically and on MR images, can occur distal to the level of the fistula; this can become particularly disorienting near the cervicomedullary junction, where the fistula can be intracranial but the myelopathy cervical to thoracic or vice versa.^{8, 18, 33, 92} Disruption of such a fistula can produce subarachnoid hemorrhage at a distance from the lesion.⁴⁹

MRI typically shows hyperintensity on T2-weighted images, possible cord enlargement, and, at times, cord enhancement secondary to infarct.⁶⁵ The high vascular flow usually produces the expected flow voids in the vicinity of the fistula on MR images or dilated vessels on myelography.⁴¹ Of interest, a surrounding peripheral rim of hypointensity on T2-weighted images has been reported with these fistulas, which may be specific in the absence of associated hemorrhage.⁵³ CT can be used to evaluate these fistulas immediately after endovascular embolization to confirm occlusion of the entire shunt.²⁰

Intradural Arteriovenous Fistulas

Intradural AVFs lie on the cord surface, where they are further subdivided by size: type I, small; type II, larger, with dilatation of the artery and vein; and type III, largest, with multiple feeders and marked venous dilatation.² A variant on this classification defines type I as those draining only to meningeal veins, type II to meningeal veins and then retrograde to subarachnoid veins, and type III to subarachnoid veins only.⁷ On MRI examinations, these lesions often appear with cord enlargement, edema, hyperintense signal on T2-weighted images, areas of enhancement, and abnormal flow voids.^{65, 122} Spiral or multislice CT scanners enable precise localization of the fistula, which allows a greater degree of treatment planning, particularly demonstrating the relationship to surrounding bone.⁴⁸

Cavernous Angiomas

Cavernous angiomas are most often intramedullary, and the risk to the patient is of hemorrhage into functioning tissues. Cavernous angiomas can be found at any cord level, and they are multiple in a significant minority of cases.^{22, 127} These angiomas show a typical reticulated pattern of heterogeneous signal intensity on all MR sequences, producing the classic "popcorn" appearance best demonstrated on T2-weighted sequences.¹⁵ This pattern, in association with a family history, other lesions in the neural axis, and a tendency toward diminished signal intensity over time, can confirm the diagnosis.¹²⁵

Neoplasms

Intramedullary neoplasms consist of (1) primary cord neoplasms (e.g., ependymomas and astrocytomas) and, to

a lesser extent, (2) hemangioblastomas, (3) intramedullary metastases, and (4) other even less common entities (e.g., intramedullary lipomas). In adults, intramedullary neoplasms comprise 7% to 22% of all spinal neoplasms and include, in decreasing order of frequency, ependymomas (65%); astrocytomas (25%); glioblastoma (7.5%); and rare hemangioblastomas, oligodendrogliomas, and metastases.^{91, 105, 109, 113} Intramedullary metastases are usually not neural in origin; lung cancer is the most common primary tumor to metastasize to the cord, followed by breast cancer. Lymphoma, colon and renal tumors, head and neck carcinoma, and melanoma also metastasize to the cord but less commonly.^{12, 23, 43} In children, intramedullary lesions account for one third of spinal neoplasms and include astrocytomas (58%), ependymomas (28.5%), teratomas, and dermoid or epidermoid tumors (5.8%).

Hemangioblastomas and intramedullary metastases, such as glioblastoma, primitive neuroectodermal tumor, and Wilms' tumor, occur infrequently in the spinal cords of children.^{17, 26, 32, 81}

Diffuse fusiform or focal expansion of the cord with loss of the normal cord contour and resultant distortion of the surrounding subarachnoid space is the hallmark of intramedullary tumors on MR images as they are on CT myelograms. Differentiation between the white matter tracts and the butterfly or H-shaped central gray matter may often be obtained with high-resolution MRI.¹¹² MRI can also be used to demonstrate the longitudinal extent of abnormal signal and enhancement as well as the internal derangement of spinal parenchymal architecture. These abilities have established the superiority of MRI over other neuroimaging techniques in the evaluation of intramedullary processes.

Traditionally, CT myelography demonstrated intramedullary masses as expansile lesions of the spinal cord, displacing the intrathecal contrast material within the subarachnoid space peripherally; occasionally, however, intramedullary lesions are not shown to expand the cord. One series noted a normal myelographic appearance in 42% of patients with intramedullary neoplasms.⁴³ Abnormal signal on standard or fast spin-echo T2-weighted images and abnormal contrast enhancement confirm the presence of intramedullary neoplasms on MRI despite lack of cord expansion.¹¹⁸ Exophytic growth of intramedullary lesions, most commonly in the region of the conus medullaris, may result in both focal cord expansion and cord displacement by the exophytic process. Exophytic growth of intramedullary lesions has been described in astrocytomas, mixed gliomas, ependymomas, and hemangioblastomas.

With early imaging and contrast enhancement, it is possible to locate intramedullary parenchymal lesions within specific quadrants of the spinal cord or within the central canal of the cord. Intramedullary neoplasms, however, are usually relatively large when initially imaged, and they distort the parenchyma of the cord over the length of several segments. Signal intensity changes of most intramedullary processes are nonspecific, and it is often impossible on unenhanced MRI to differentiate neoplasm from associated edema or postoperative gliosis because of similar nonspecific T1 and T2 lengthening.^{27, 94, 110, 129} Tumor

and edema have similar MRI characteristics, whereas associated cysts may become more hyperintense on T2-weighted sequences than the adjacent abnormal cord. Features that help distinguish tumor-related cysts from syringes include abrupt changes in diameter and position of the cyst, uneven thickness of the surrounding cord, increased T2-weighted signal of tumor cysts, and pathologic enhancement.^{106, 126} Cystic lesions associated with tumor, however, may not be well defined without contrast administration.^{16, 42}

After administration of contrast, there is striking and immediate enhancement of most intramedullary neoplasms on both CT scans and MR images. The focus of enhancement is usually smaller than the region of abnormal signal and spinal cord enlargement defined on the unenhanced views, helping to localize the actual neoplastic focus.^{64, 79, 117} Occasionally, lesions fail to enhance and may be identified by abnormal signal intensity only.

Unfortunately, enhancement patterns are nonspecific, although astrocytomas tend to enhance in a more irregular manner compared with ependymomas or hemangioblastomas and are often eccentrically located. Cystic degeneration tends to indicate astrocytoma, whereas signal changes consistent with pigment or fat/calcium tend to indicate melanoma or teratoma, respectively.⁶⁹ Ependymomas and hemangioblastomas both enhance homogeneously and are more likely to be associated with cysts and syringes. Up to 75% of hemangioblastomas are cystic, and draining veins and cord edema, probably secondary to vascular shunt-related congestion, may also be seen in hemangioblastomas.^{21, 44, 89, 111} Heterogeneous signal on T1-weighted and T2-weighted images, hypointensity at the tumor margins resulting from firm pseudocapsule formation, and intratumoral hypointensity from hemorrhage suggest ependymoma.^{69, 86}

Ependymomas

Ependymomas represent 65% of spinal cord neoplasms. They are found more commonly in men and usually present between 20 and 60 years of age. They represent the most common glial tumor of the lower cord. Three quarters are myxopapillary subtypes and arise within the conus or filum terminale, and the remainder are found in the cervical and thoracic cords. Ependymomas within the cervical and thoracic cords are generally indistinguishable from astrocytomas; however, astrocytomas are far more common in the cervical cord and slightly more common in the thoracic cord than ependymomas.⁷⁸

Ependymomas are usually histologically benign and slowly growing, which generally allows them to reach a large size by the time they manifest clinically. They may span one to five vertebral body segments and are highly vascular, often resulting in intratumoral hemorrhage that can be visualized on imaging.¹³² They may be large enough to produce marked expansion of the spinal canal, and the vertebral bodies on either side of the disk may be excavated, with the pedicles and neural arches eroded. Smaller ependymomas tend to displace nerve roots, whereas larger tumors tend to engulf adjacent nerve roots and may become indistinguishable from them.

Ependymomas appear isodense to hypodense on nonenhanced spinal CT and enhance after the intravenous (IV) administration of contrast material. Although calcification has been reported to be common in posterior fossa and supratentorial ependymomas, it has not been commonly observed in spinal cord ependymomas. Ependymomas of the cauda equina are reasonably characteristic, usually appearing as a spherical mass centrally within the spinal canal. After administration of a water-soluble contrast agent, myelographic and postmyelographic CT scans demonstrate the nerve roots of the cauda equina above and below the tumor mass, thus delineating the conus as separate from the mass.

The MRI appearance of spinal ependymomas is variable, depending on the location within the spinal cord. In the cervical and thoracic regions, they appear as expansile lesions of the cord in the sagittal and axial planes and are slightly hypointense on T1-weighted images and hyperintense on T2-weighted images. In addition, intratumoral cyst cavities have occasionally been reported in these locations.¹³² In the cauda equina region, the tumors are typically spherical masses with signal intensities similar to those found elsewhere (Fig. 24-5). Because of possible episodes of rebleeding from the fibrovascular stroma, however, repeated episodes of subarachnoid hemorrhage may lead to hemosiderin deposition within the subarachnoid space. This appears as areas of marked hypointensity on T2-weighted images.¹³² Gadolinium enhancement is generally in a homogeneous, well-circumscribed pattern, rendering the lesion more conspicuous.

Astrocytomas

Astrocytomas represent one third of intramedullary gliomas and may occur at any location along the cord. They are most common between 20 and 50 years of age and are slightly more common in men. Seventy-five percent of these tumors are low-grade (grade I or II). Astrocytomas tend to occur in the cervical and thoracic segments, where they have an incidence equal to or greater than that of ependymomas. In children, the proportional incidence of astrocytomas to ependymomas is higher than that in adults.¹³²

Intratumoral cysts within astrocytomas, as well as syringomyelia at one or both ends of the cord associated with astrocytomas, occur with variable incidences. Most astrocytomas are solitary tumors, but they can be multiple in the case of neurofibromatosis. Histologically, the low-grade tumors are fibrillary astrocytomas with pilocytic features. On noncontrast CT scans, astrocytomas of the spinal cord appear as hypointense to isointense lesions.⁸⁵ After administration of IV contrast material, these lesions often enhance heterogeneously, with nonenhancing portions of tumor representing intratumoral cyst cavities.⁴⁵ Water-soluble myelographic scans demonstrate fusiform enlargement of the spinal cord, with focal nodules or abrupt changes in size indicating the likelihood that the cord mass represents a tumor and not a syrinx. Syringes at either end of the tumor generally have a sausage-like appearance, being uniformly expanded and lacking any focal nodules. Calcification within astrocytic tumors of the spinal cord is not common.¹³²

Figure 24-5. Conus myxopapillary ependymoma. A, T1-weighted sagittal MR image shows a hypointense expansion of the conus. B, T2-weighted sagittal MR image demonstrates an exophytic cystic lesion of the conus that contains a fluid-fluid level.

MRI is the best way to demonstrate enlargement of the spinal cord by an astrocytoma (Fig. 24-6). Sagittal and axial plane images demonstrate expansion of the cord. T1-weighted images demonstrate astrocytomas to be low in signal intensity whereas proton-density-weighted and T2-weighted images show them to be high in signal intensity.^{107,129} Intratumoral cysts are irregular areas; their contents reflect a signal intensity similar to that of CSF. Syrinxes at either end of the tumor demonstrate parallel walls, and their contents also demonstrate signal intensity similar to that of CSF. Axial images demonstrate the asymmetrical expansion of the cord by tumor tissue. Astrocytomas tend to enhance more heterogeneously than ependymomas, partly because of the high incidence of intratumoral cysts, and IV gadolinium administration aids in the detection and characterization of astrocytomas.⁹⁴

Hemangioblastomas

Hemangioblastomas are uncommon tumors of the spinal cord, representing 1.6% to 3.6% of spinal cord tumors; they are most often found in association with von Hippel-Lindau disease.¹³² They are usually found in middle-aged adults, demonstrate no sexual predilection, and are solitary in 80% of cases. Although they are usually solitary, hemangioblastomas may be multiple in von Hippel-Lindau dis-

ease. Approximately 50% of hemangioblastomas are cystic with a mural tumor nodule. The cysts are often high in protein content and are suggestive of prior episodes of hemorrhage.¹³² The tumors may arise in the cervical or thoracic cord, usually causing diffuse focal widening of the cord.

On nonenhanced CT scans, the tumor nidus appears isodense to slightly hyperdense in attenuation, and after administration of IV contrast material, the tumor markedly enhances; the enhancing tumor nodule appears distinct from the associated cyst. On contrast myelographic scans, the spinal cord appears enlarged with multiple serpentine filling defects from arteries and veins that result from this relatively vascular tumor.¹³²

MR images demonstrate an enlarged, infiltrated spinal cord, and in half the cases a cyst containing a mural nodule can be identified. A large syrinx may also accompany the tumor, helping to support the diagnosis.⁹⁴ Gadolinium enhancement (Fig. 24-7) is the most useful technique to differentiate the mural tumor nidus from the associated reactive, cystic changes.^{94, 116, 117}

Intramedullary Metastases

Hematogenous metastases to the spinal cord from a primary site outside the CNS (lung, breast, melanoma) are

Figure 24-5. *Continued, C.* A postcontrast T1-weighted sagittal MR image shows the sharp rim enhancement of the tumor. *D* and *E.* A postcontrast T1-weighted axial section demonstrates compression of the conus by the enhancing cystic mass.

rare, even when there are metastatic lesions to other spinal structures, such as the vertebral bodies and the epidural space.³⁰ Of the tumors of non-neurogenic origin metastasizing to the cord, lung carcinoma is the most common (Fig. 24-8), and breast carcinoma is the second most common. Other reported primary tumors are much less common; they include lymphoma, melanoma, colorectal carcinoma, Hodgkin's disease, head and neck carcinoma, and leukemia.⁹⁹

Drop metastases from primary brain tumors can seed down the central canal of the spinal cord and produce an appearance similar to that of an intramedullary metastasis. These metastases are usually from malignant gliomas, ependymomas, medulloblastomas, and pineal tumors. Although apparent on CT myelograms, these, like other lesions, are best detected by MRI with contrast enhancement.⁵⁰

In most instances, the intramedullary metastatic lesion

is small and does not produce significant mass effect. Therefore, a discernible change in the size of the spinal cord cannot be noticed on either contrast-enhanced myelographic or postmyelogram CT scans.¹³⁰ In a few instances, focal enlargement of the cord may be sufficient to be seen by either modality.

MRI is the best technique for evaluating intramedullary spinal cord metastatic lesions. Enlargement of the spinal cord, even when subtle, is best seen on T1-weighted images in the sagittal plane and is the first indication of an intramedullary lesion. Lesions are hyperintense on T2-weighted images and generally enhance heterogeneously after IV gadolinium administration (Fig. 24-9). T2-weighted signal intensity changes and abnormal enhancement can be seen in the absence of cord enlargement.⁹⁹ Subsequent to the intramedullary metastasis, a blockage and then dilatation of the central canal can occur, producing a typical syrinx in association with the mass.^{56,97}

Figure 24-8. Intramedullary drop metastases to the cord from lung metastasis. A, T2-weighted, fast spin-echo, sagittal MR image shows a band of hyperintensity along the posterior cord. B, Postcontrast T1-weighted sagittal MR image demonstrates a heterogeneously enhancing ovoid mass in the lower thoracic cord. C, This T1-weighted axial section shows an eccentric hypointensity without definite distortion of the cord surface. D, This T1-weighted postcontrast axial section confirms the homogeneous enhancement of the mass.

Figure 24-9. Hematogenous metastasis to the conus medullaris from lung carcinoma. *A*, T1-weighted sagittal MR image shows expansion of the inferior cord. *B*, T2-weighted sagittal MR image demonstrates abnormal hyperintense signal in the conus and a more focal area of greater signal intensity. *C*, Postcontrast T1-weighted sagittal MR image shows heterogeneous enhancement extending over the length of more than one vertebral body of the lower cord. *D*, A gradient-echo, FLASH (fast low-angle shot), T2-weighted axial section confirms cord expansion and the central signal intensity abnormality. *E*, Postcontrast T1-weighted axial section highlights a focal area of greater enhancement.

Infection, Inflammation, and Demyelination

Infectious diseases typically occur around the spinal cord, as in osteomyelitis, diskitis, and epidural abscesses, but more rarely they can involve the intramedullary substance. Cord infection can be expected to produce decreased signal with T1 weighting, increased intensity on T2-weighted images, and early variable enhancement with gadolinium, representing myelitis or abscess.⁸³ These lesions occur as a result of hematogenous dissemination and can arise, for example, from typical pyogenic bacteria, in syphilis or in tuberculosis.^{40, 84} The myelitis can have associated enhancement that may resolve after successful antimicrobial therapy, whereas frank abscesses can show typical rim enhancement.^{57, 84} A congenital lesion, such as a dermal sinus, can allow formation of an unusually high number of intramedullary abscesses.²⁵

Intramedullary involvement in the prototypical granulomatous diseases, tuberculosis and sarcoidosis, is rare. When the cord is involved in tuberculosis, an enhancing intramedullary tuberculoma is expected, but fewer than 150 examples have been reported among patients with normal immune systems.¹⁰¹ In patients with acquired immunodeficiency syndrome (AIDS), this entity may arise slightly more often, but the tuberculoma has a nonspecific appearance, its signal intensity is decreased on T1-weighted images and increased on T2-weighted images, and peripheral or nodular enhancement is seen.⁷⁶ Very rarely, a frank abscess within the cord arises, at times in association with meningitis of tuberculosis.¹¹⁹

CNS involvement in systemic sarcoidosis occurs in about 5% of patients, but direct primary cord lesions have

been reported in fewer than 100 cases. In the cord, this disease also has a nonspecific appearance, with cord enlargement and multifocal patchy areas of enhancement, again frequently in association with meningitis.⁸⁷ These lesions should resolve, however, after appropriate steroid therapy, perhaps with the exception of infrequently reported central calcifications.^{95, 128}

Parasitic myelitis can produce a similar appearance in association with a CSF eosinophilia.⁶³ Although rare, typical parasitic diseases have been reported to involve the spinal cord: schistosomiasis,²⁹ toxoplasmosis in patients with AIDS,^{98, 103} and cysticercosis. When schistosomiasis invades the cord, it can cause a nonspecific myelitis, or the ova can induce formation of granulomas that can be identified on CT myelograms.⁴⁶ In patients with cysticercosis, syringomyelia or cystic intramedullary lesions can be present and are associated with brain parenchymal lesions.⁶⁸

Involvement of the spinal cord as a direct result of fungal disease occurs only rarely and typically only in those with significant immune compromise. Aspergillosis is the most common fungal disease of the cord, typically presenting as a myelopathy but also reported as occluding principally the anterior spinal artery.^{59, 96} Cord abscesses caused by *Candida*, *Coccidioides*, and *Nocardia* have been reported.^{1, 70, 82} Similarly, cord granulomas caused by *Cryptococcus* and *Histoplasma* have been described in isolated reports.^{55, 114}

Viral infections of the spinal cord are encountered most often among patients with immune compromise. In patients with AIDS, intramedullary infection with human immunodeficiency virus type I (HIV-1) causes a vacuolar myelopathy that shows nonspecific hyperintensity on T2-weighted images.^{3, 124} Herpes zoster typically affects the skin but can produce a myelitis that shows cord enlargement, hyperin-

Figure 24-10. Degenerative changes of the spine with cord effect. A, T2-weighted FLASH (fast low-angle shot) axial section demonstrates a posterior disk-osteophyte complex impressing upon the thecal sac and the central cord. B, T2-weighted fast spin-echo sagittal MR image confirms the degenerative changes along the posterior vertebral line and demonstrates nonspecific abnormal hyperintensity within the substance of the cord at the C6 level.

tensity on T2-weighted images, and variable enhancement.^{38,51} Cord involvement by the Epstein-Barr virus has been reported as either encephalomyelitis or isolated myelitis, demonstrating the same nonspecific findings as the preceding viral disorders.^{13,28}

Degenerative and demyelinating disorders can cause an acute transverse myelitis, or myelopathy. When the spinal canal narrows because of degenerative changes in the bones, joints, and disks, pressure to the cord can occur that will cause myelopathic changes visible on MR images (Fig. 24-10). The causes are uncertain and may include edema, inflammation, ischemia, or gliosis.⁷⁵

The lesions of multiple sclerosis, the prototypical demyelinating disease, tend to be located at the cervical level, although they can be found throughout the medullary substance, whereas the lesions of idiopathic myelitis tend to appear at the thoracic levels.^{19,66} The lesions of multiple sclerosis often demonstrate multiplicity within the CNS, underscoring the need for separation in time and space to diagnose this multiphasic disease.

In contrast, acute disseminated encephalomyelitis arises as a monophasic illness after exposure to a viral vaccine; multifocal plaques may appear, but they do not recur after improvement, which is slow.²⁴ In the rare instances when these plaques do recur in the absence of a diagnosis of multiple sclerosis, other autoimmune disorders, perhaps

involving the presence of anti-cardiolipin antibodies, may be considered.¹⁴ A delayed postradiation myelopathy can occur, but the diagnosis remains one of exclusion, with nonspecificity of the signal changes and enhancement on MR images.⁵⁸ Collagen vascular diseases, in particular in 1% to 2% of patients with systemic lupus erythematosus, can also cause a transverse myelitis that rarely affects the entire cord.^{62,88}

Unfortunately, the lesions of all these disorders have a similar appearance: hyperintense plaques within the cord substance on T2-weighted images, possible cord enlargement, and possible enhancement. Only the spinal cord enlargement can be well seen on CT scans; thus, the modality of choice is MRI, in which the absence of cord expansion has become the best predictor of a non-neoplastic cause to an unknown cord lesion.^{67,77} These lesions are best depicted with fast STIR (short tau inversion recovery) sequences, and in contrast to similar lesions in the brain, they are not well demonstrated by FLAIR (fluid-attenuated inversion recovery) sequences (Fig. 24-11).^{52,54}

In multiple sclerosis, the most common source of myelitis seen in the United States, lesions tend to occur in multiples (Fig. 24-12), to be eccentrically located (Fig. 24-13), to involve less than half the cross-sectional area of the cord, and to extend less than two vertebral bodies in length.¹²⁰

Figure 24-11. Multiple sclerosis plaque. A, A FLAIR (fluid-attenuated inversion recovery) sagittal MR image shows the lesion within the anterior cord centered at the third thoracic vertebra. B, The same lesion is even better demonstrated by the fast spin-echo T2-weighted sequence, and its appearance is not significantly diminished because of the high signal from the surrounding cerebrospinal fluid.

Figure 24-12. Multiplicity of multiple sclerosis plaques. *A* and *B*, These fast spin-echo, T2-weighted MR images reveal a larger ovoid area of hyperintensity centered at C5 (*A*), and a second smaller, rounded lesion more superiorly at the level of C2–C3. *C*, An axial FLASH (fast low-angle shot) gradient-echo sequence produced this axial image showing two side-by-side lesions, the larger to the patient's right.

Figure 24-13. Eccentricity of multiple sclerosis plaques. *A*, A STIR (short tau inversion recovery) sagittal MR image shows a broad ovoid hyperintensity along the anterior cord at C4. *B*, The postcontrast T1-weighted sagittal MR image reveals eccentric anterior rim enhancement. *C*, The postcontrast T1-weighted axial section demonstrates a low level of rim enhancement eccentrically positioned in the right anterior quarter of the cord.

Figure 24-14. Systemic lupus erythematosus. A, T1-weighted sagittal MR images demonstrate cord enlargement at the conus. B, FLASH (fast low-angle shot) gradient-echo axial section shows abnormal hyperintense signal of the central gray matter consistent with cord ischemia secondary to a lupus vasculitis. C, A high T2-weighted axial section from the cervicomedullary junction shows similar abnormal signal in the bilateral posterior substance.

The relevance of enhancement depends on the underlying cause. In infection, it represents a more mature myelitis moving toward abscess; in demyelination, it represents acuity of the process with concurrent active destruction of myelin.⁶⁶ Some have reported an increased specificity when diagnosing lesions after gadolinium enhancement in multi-

ple sclerosis.¹²¹ Yet, any or all of these findings, including abnormal signal, cord thickening, and enhancement, can be seen in each of these disorders, even the more rare manifestations such as lupus¹⁰⁰; indeed, some, as in lupus, may even appear indistinct from other causes of spinal cord infarct on MR images (Fig. 24-14).

Magnetic Resonance Imaging of Infections of the Spine

Charles F. Lanzieri

Because infections of the spine present with subtle and nonspecific symptoms, they represent a diagnostic problem, and imaging plays a key role in the initial diagnosis and subsequent management. Clinical symptoms, which commonly include fever, malaise, back pain, and focal tenderness, are often insidious in onset and can be attributed to a variety of common conditions. By the time focal neurologic findings such as extremity weakness or meningismus appear, the stage is set for rapid progression to permanent neurologic deficits at worst and a chronic state of osteomyelitis at best. The infection can rapidly spread to the epidural space with concomitant paraplegia. Delayed diagnosis increases the morbidity and mortality of spinal infections; diagnostic imaging is therefore critical.

Infection of the spine initially involves either the disk space or the vertebral body, and spread occurs via the arterial or venous system or by direct inoculation during diagnostic procedures. Pyogenic infections evolve more rapidly than nonpyogenic infections, which have a more indolent course. Pyogenic infections are commonly caused by *Staphylococcus aureus*, which accounts for about 60% of this category of infection.^{2, 5, 12} The most common cause of the nonpyogenic infections is *Mycobacterium tuberculosis*. Specific pathogens are more common in patients with predisposing conditions. For example, *Salmonella* is a common cause of osteomyelitis in patients with sickle cell disease, and *Serratia* and *Candida* are commonly seen in patients using intravenous drugs. The course of nonpyogenic infections is even more insidious and has a slower evolution than that of pyogenic infections. Infections caused by the tubercle bacillus or fungus are very difficult to diagnose.

Before cross-sectional imaging in the 1980s, radiologic diagnosis of disk space infections and vertebral osteomyelitis depended on interpretation of plain radiographs and radionuclide studies. Radiographs are usually unrevealing for the first 2 to 8 weeks of the disease process. Radionuclide studies have demonstrated incorporation of technetium 99m in 80% of infected bone sites by the 10th day of the infection.¹⁵ These examinations, however, have significant limitations, most notably false-positive results. Radionuclide bone scans cannot reliably differentiate cellulitis from osteomyelitis. False negatives also occur when the blood supply to the infected bone or disk space is impaired.

The use of high-resolution computed tomography (CT)

was found to be very useful because of its ability to demonstrate bone destruction or focal osteopenia early in the course of the infection. Its ability to demonstrate prevertebral soft tissue swelling and cellulitis, however, was disappointing.

Magnetic resonance imaging (MRI) quickly became the study of choice for evaluating patients with spinal complaints. Its advantages include multiplanar capability, superior soft tissue contrast resolution, and a unique ability to detect end-plate, disk space, and marrow changes. In addition, MRI can demonstrate subtle changes far earlier in the course of the disease than previously employed techniques. Finally, MRI is extremely useful for following patients with proven spinal infection and for planning aspirations or other interventions. This has a direct impact on patient management. MRI has dramatically changed the outcome of patients with spinal infections over the last 10 years.

Pathophysiology

Infectious processes can extend to the spine by several mechanisms. Direct extension occurs secondary to trauma or surgical intervention for reasons other than infection. Diagnostic lumbar punctures or epidural injections as well as surgery for herniated disks are common causes. Contiguous spread can occur from adjacent infected structures. Hematogenous spread can come from distant sites. A source of hematogenous dissemination can be found in up to half of the patients with spinal osteomyelitis.⁴ The most common sources are the genitourinary tract, the skin, and the respiratory tract.¹⁸ The arterial system is thought to be a much more common route of spread to the spine, although extension via the epidural venous plexus occurs via the pelvic plexus of veins.¹⁹

A number of events occur during the first few weeks of infectious spondylitis. The organism commonly settles in the anterior portion of the subchondral bone marrow. The infection then spreads within the marrow space or into the adjacent intervertebral disk, causing osteomyelitis and/or diskitis. Nonpyogenic infection may spread into the subligamentous space, and from there it may penetrate the ligament and the adjacent soft tissues. Disk-sparing infections of adjacent vertebral bodies are a common sign of tubercle bacillus infection.⁵ Both pyogenic and nonpyo-

genic infections tend to remain within the vertebral body and disk spaces and do not usually involve the posterior elements and adjacent ligaments and soft tissues. This type of involvement is more typical of metastatic disease.

Although pyogenic infections rarely involve the posterior elements, tuberculosis (TB) sometimes does. The level most often involved in TB spondylitis is L1, but the thoracolumbar junction is most affected in general. The cervical and lumbar levels are less frequently involved.

Following successful therapy for infection, the reparative process can include partial or complete bony ankylosis of the disk space. Without adequate or proper therapy, bony lysis occurs, with subsequent collapse of the vertebral body. In nonpyogenic infections such as TB, anterior wedging with secondary kyphotic deformity occurs.

Pyogenic Disk Space Infections

Pyogenic infections, which have a peak incidence in the sixth and seventh decades of life, are caused by both gram-positive and gram-negative bacteria. The dominant inflammatory cell is the polymorphonuclear leukocyte. Both the vertebral body and the adjacent disk space become involved. The cancellous bone adjacent to the cartilaginous end plate is richly vascular throughout adulthood, which makes it a common site for visitation from hematogenously borne pathogens. The infection then spreads across the disk to involve the adjacent vertebral body. Most of the time, the infection is limited to the disk space and the two adjacent vertebral bodies. In about 25% of cases, multiple

levels are involved.⁸ Infectious agents settle in the most vascular spaces in the spine.

In children, who have a rich vascular supply in and around the disk spaces, infections can spread directly to the disk.⁵ In adults, the disk space is nearly avascular; therefore, infections begin in the subchondral bone adjacent to the end plate, which is very vascular throughout adulthood. Pyogenic infections are often self-limited in children and may be cured with bed rest and antibiotics.

The population most commonly affected by vertebral osteomyelitis consists of adults in the sixth to seventh decade of life. The lumbar spine is the site most commonly affected, followed by the thoracic and cervical spine. Men are affected more often than women, at a ratio of two to one. Treatment with parenteral antibiotics for about 6 weeks is usually required for cure. Surgical intervention is necessary when there are neurologic findings and an epidural mass is identified, or when there is secondary instability and fusion needs to be performed.

Radiographic findings are usually subtle and may not appear until relatively late in the process (Fig. 25-1). The hallmark of disk space infection on plain radiographic examination is disk space narrowing. This is followed by erosion of the adjacent end plates. It may be several days or weeks before these findings are evident. The characteristic findings of disk space narrowing and end-plate irregularity may not be seen until the fourth week of the infection. Prominence of the retropharyngeal soft tissues is a variable finding. Plain films cannot demonstrate the important intraspinal complications of infection that are ultimately responsible for neurologic symptoms. CT is very useful in

Figure 25-1. Lumbar disk space infection with osteomyelitis.

A, T1-weighted sagittal MR image through the lumbar spine. The arrow indicates a disk space infection at the L1-2 level. The normal cortical dark line along both articular surfaces, especially along the inferior surface of L1, is not visible. A decrease in the signal coming from the marrow fat in both vertebrae indicates the presence of marrow edema.

B, T2-weighted image in the same location shows edema in the marrow and slightly increased signal in the interspace. Although the disk space at L1-2 is not brighter than the adjacent disk spaces, the normal internuclear cleft is lost. In addition, a much lower signal would be expected in a partially collapsed and degenerated disk.

C, Post-contrast-enhanced image in the same location. Although the disk space itself does not show enhancement, the vertebral bodies do. The arrow indicates loss of the anterior cortical margin of L1, a sign of upward spread of infection.

these patients because it is more sensitive than plain film. In addition, the soft tissue changes begin to become evident.

MRI offers the best opportunity to image and confirm vertebral infections early in their course. The first MR findings reflect the replacement of normal bone marrow by inflammatory tissue and edema in association with structural changes such as disk space narrowing.¹⁰ The sensitivity of MRI for disk space infections is the same as that of radionuclide studies and the specificity is much higher. Even early studies using nonenhanced MRI showed a sensitivity of 96%, a specificity of 92%, and an accuracy of 92%.¹⁰ Evidence of vertebral osteomyelitis appears at about the same time on MRI as it does on gallium or technetium 99m radionuclide studies.¹⁰

Marrow replacement first appears as decreased signal on T1-weighted images because of edema or infiltration of fat in the bone marrow. On T2-weighted images, marrow

edema is reflected as increased signal because of the additional water content in the marrow. A band of increased signal in the subchondral bone marrow is highly suggestive of pathologic change in the adjacent disk space. Unfortunately, this change is somewhat nonspecific and can be seen in a variety of conditions including recent trauma and early degenerative disease. Changes in the disk space are seen on both T1-weighted and T2-weighted images. On the T1-weighted images, narrowing of the interspace with slight loss of signal can usually be visualized.

The most dramatic, recognizable, and reliable sign of disk space infection on MRI is the increased signal seen on T2-weighted images. In adults, this is accompanied by loss of the normal band of decreased signal that represents what is referred to as the intranuclear cleft. These findings may be supported by the observation of swelling and edema in the adjacent soft tissues (Fig. 25-2). When the

Figure 25-2. Lumbar disk space infection with osteomyelitis and paraspinal cellulitis. *A* and *B*, Sagittal T2-weighted images through the lumbar spine. Bright signal is associated with the L2-3 intervertebral disk. This is the hallmark of diskitis on an MRI scan (*arrow*). *C*, Post-contrast-enhanced axial T1-weighted image. Enhancement can be visualized in and around the L2-3 interspace, as well as in the paraspinal soft tissues and within the spinal canal. These represent paraspinal and epidural cellulitis. If left untreated, they could progress to abscess formation.

bony cortex of the vertebral body becomes involved, the normally dark cortical margin on all MRI sequences can no longer be visualized. This implies osteomyelitis. If intravenous contrast material is given, enhancement within the disk space and in the adjacent vertebral bodies usually increases diagnostic confidence.¹³

Some pitfalls exist in diagnosing disk space infections using MRI. The intermediate changes seen in degenerative disk disease may mask the early changes of a disk space infection. Both processes produce low signal on T1-weighted images. In the case of degenerative disease, the infiltration of fat into the subchondral portion of the vertebra is an intermediate change that increases the T1 signal intensity. Since infection lowers the degree of T1 signal, a canceling effect occurs that potentially masks the edema. The T2-weighted images should be reviewed carefully to search for edema in suspected infections. Occasionally, a degenerated disk transiently contains cystic areas. This causes increased signal on T2-weighted images and mimics one of the hallmarks of diskitis, a bright interspace.

Although many disk space infections represent hematogenous seeding, a significant number are secondary to surgery involving the disk space. Disk space infections follow up to 3% of surgical procedures on the spine.⁵ Clinical

Figure 25-3. Cervical disk space infection. Disk space infections and diskitis are unusual occurrences in the cervical spine. T2-weighted sagittal image shows increased signal in the C3-4 intervertebral disk space and edema in the adjacent bone marrow fat (arrow). The cortical margins remain intact and there is no evidence of a paraspinal abscess. Increased signal in the adjacent spinal cord represents the presence of myelomalacia from chronic cord compression. Although this patient had not had previous surgery, the same appearance is seen following cervical discectomy.

suspicion is raised when, in the first few postoperative weeks, patients present with back pain radiating to the extremities and signs of infection such as elevated white blood cell count, an elevated sedimentation rate, and fever. Because signal changes in the vertebral bodies, disk spaces, and adjacent soft tissues occur following surgery, the diagnosis of postoperative infection is difficult.

Cervical vertebral osteomyelitis and diskitis are usually diseases of older people, but they occur frequently in younger patients who are intravenous drug abusers (Fig. 25-3).¹⁶

Epidural Abscesses

Epidural abscesses can occur either spontaneously or secondary to disk space infection and osteomyelitis. Imaging greatly improves patient outcome because a specific diagnosis based only on clinical signs and symptoms is impossible and early treatment is important. MRI is the study of choice when an epidural abscess is suspected and results are positive before radionuclide scanning.¹ Clinical signs and symptoms include back and radicular pain, stiffness, and cramping. Rapid expansion can result in permanent neurologic deficits, the result of direct cord or root compression in most cases, with secondary white matter injury. Vascular thrombosis and direct infiltration of the cord or roots are less common.

Although MRI and myelographic CT are similar in sensitivity for identifying epidural abscesses,¹⁰ MRI offers the ability to distinguish between causes of epidural masses. Thus MRI can differentiate epidural abscess from hematoma, tumor, or disk fragment (Fig. 25-4). Because it is noninvasive, it is the obvious first choice for imaging. Epidural abscesses appear as isointense masses on T1-weighted images, and the intensity is frequently increased on T2-weighted images.¹² Patients with epidural abscess almost always have accompanying meningeal thickening and enhancement.

Without contrast injection, any fluid collection in, or necrotic portion of, the subarachnoid or epidural space can be overlooked. Although not necessary for the diagnosis of disk space infections, contrast-enhanced MRI is essential for the accurate diagnosis of abscess collections in the epidural space (Fig. 25-5). With contrast injection, epidural abscesses are easily demonstrated. Homogeneous enhancement of the mass is seen, with central necrosis indicating a focal fluid collection. Most abscesses occur adjacent to an infected interspace and generally spread to between two and four vertebral levels. Rarely, extension may involve the entire length of the spine.¹⁴

Tuberculosis

Tubercle bacillus infections are more insidious than pyogenic infections of the spine. As in pyogenic infections, the initial symptoms are nonspecific and early diagnosis is

Figure 25-4. Cervical disk space infection with epidural abscess. *A*, T2-weighted sagittal image through the cervical spine. The C5-5 intervertebral disk space has increased signal, indicating the presence of diskitis. Although there is no evidence of adjacent marrow edema and the cortical margins are intact, a region of increased signal in the paraspinal soft tissues anterior to the interspace (arrow) indicates the presence of paraspinal cellulitis. *B*, T1-weighted sagittal image reveals contrast enhancement of the interspace, which confirms disk space infection. Thickening and enhancement of the meninges in the cervical spine and a small epidural fluid collection in the epidural space (arrow) indicate the presence of an epidural abscess.

difficult. In the case of TB, the symptoms may last for months or years prior to diagnosis. Tuberculous vertebral osteomyelitis remains a significant medical problem in developing countries.

The skeleton is the most common extrapulmonary site of involvement, and spinal TB occurs in 50% of the cases of skeletal TB. Vertebral osteomyelitis is estimated to occur in 0.03% of all TB cases.⁷ The TB bacillus spreads to the vertebral body hematogenously and, like pyogenic organisms, lodges in the anterior and subchondral portion of the vertebral body. The granulomatous inflammatory response to the bacillus results in a tubercle, which then invades the surrounding soft tissues and forms a tuberculous abscess. As the abscess grows, the periosteum and the longitudinal ligaments of the spine are elevated and the abscess extends up and down the spine to involve adjacent vertebra. The thoracolumbar junction is most frequently involved; involvement of the cervical and thoracic spine is unusual. Classically, spinal tuberculosis initially involves the anterior and inferior portion of the vertebral body (Fig. 25-6). Extension to other vertebral bodies occurs beneath the anterior and posterior longitudinal ligaments and is referred to as subligamentous spread. The disk spaces usually remain relatively spared.

Involvement of the posterior elements of vertebral bodies is more common in TB than in other forms of infection. Infection of multiple vertebral bodies and posterior elements is involved, with sparing of the disk spaces. This makes differentiation of TB from metastatic neoplasm difficult.¹⁷

Nontuberculous Granulomatous Spondylitis

The granulomatous response is a nonspecific response to an antigenic stimulus, and it is observed in a variety of pathologic conditions, including infections, neoplasms, and autoimmune diseases. The pathologic hallmark is the presence of mononuclear phagocytic cells and multinucleated giant cells. Organisms that infect the spine and cause a granulomatous reaction include the tubercle bacillus, *Brucella*, and fungi. In endemic areas of the Middle East and Asia, granulomatous spondylitis is still quite common.

Brucella is a small gram-negative coccobacillus common in cattle and swine. In the United States, the most common species are *B. abortus* and *B. suis*. When infecting humans, the organism often affects the lumbar spine. The disk space is usually spared and vertebral osteomyelitis may be accompanied by soft tissue fibrosis. The morphology of the vertebral body is preserved despite evidence of infection. The posterior elements are typically spared and the disk space is slightly reduced despite being involved with infection.

Fungal infections of the spine include coccidioidomycosis (most frequently encountered in the southwestern United States), blastomycosis (found in the central and southeastern states), and actinomycosis. The findings in fungal infections are not specific to the infecting agent. Multiple vertebral bodies are involved but the disk spaces are spared. On plain radiographs, lytic lesions with sclerotic margins are seen. Lytic bony lesions with sclerotic margins are frequently seen with sparing of the interspace. Epidural

Figure 25-5. Retropharyngeal abscess with extension to the spine. Although retropharyngeal abscesses can progress to involve the adjacent spine, the opposite can also happen.

A, T2-weighted sagittal image reveals the presence of multilevel diskitis and osteomyelitis. Vertebral bodies C4 through T1 have increased signal, and the cortical margins are lost. There has been collapse of C4 and C6 and the C4-5 and C6-7 interspaces are obliterated from previous surgery and ongoing infection. A multilevel laminectomy has been performed as part of this patient's cervical decompression.

B, Post-contrast-enhanced and fat-suppressed T1-weighted image shows enhancement within the vertebral bodies and paraspinal soft tissues anterior to the spine. A focal region of nonenhancement just anterior to C5 (*arrow*) represents the presence of a small abscess in the paraspinal soft tissues. Images **C** and **D** were obtained several days later when the patient had failed to improve on antibiotic therapy.

C, Post-contrast-enhanced T1-weighted image through C6. The *asterisk* lies within a large retropharyngeal abscess that is contiguous with the C6 vertebral body. The *curved arrow* points to the thickened and enhancing meninges. The *straight arrow* indicates the presence of a fluid collection within the epidural space. This is an epidural abscess.

D, Sagittal image also shows the retropharyngeal and paraspinal abscess (*asterisk*) and the epidural abscess (*curved arrow*).

and meningeal involvement is seen with all of these types of infections, but the *degree* of involvement is usually somewhat less than that seen with TB abscess of a similar size.

Sarcoidosis

Sarcoidosis is a noncaseating granulomatous condition that affects multiple organs in adults in the third through fifth decades. About 5% of patients have central nervous system involvement. Involvement of the vertebral bodies

is rare.⁶ In the spine, where it is most often seen in the thoracolumbar region, it usually manifests as leptomeningeal thickening, and enhancement is seen after injection of contrast material. Mixed lytic and sclerotic changes have been seen in single or adjacent vertebrae. The intervertebral disks are spared.

Intramedullary Cord Infections

The human immunodeficiency virus (HIV) causes a vacuolar degeneration of the central nervous system. In

Figure 25-6. Tuberculous spondylitis frequently mimics metastatic disease. *A*, T1-weighted sagittal image demonstrates well-defined marrow replacement posteriorly and inferiorly in the L3 vertebral body (*arrow*). *B*, On the axial image, a slightly sclerotic, superior border is better appreciated (*arrow*). This degree of new bone formation would be unusual in metastatic disease unless it had been treated. The sclerotic margin suggests a chronic inflammatory process such as tuberculosis. *C*, Post-contrast-enhanced image shows that the infection has crossed the interspace to involve the adjacent L4 vertebral body. Subligamentous spread is classic for tuberculous spondylitis.

the brain, this feature of the acquired immunodeficiency syndrome (AIDS) is recognized as focal frontal lobe atrophy or volume loss. In the spinal cord, increased signal can be seen within a short segment of the cord. This carries the general name of transverse myelitis (Fig. 25-7), and it is caused by other infectious agents as well.

In patients who have transverse myelitis but are negative for HIV, other viral infections such as herpes zoster should be considered. A variety of noninfectious causes also exist, including nutritional deficiencies, toxins, and drugs.^{3,9} Common autoimmune and demyelinating diseases, such as multiple sclerosis and lupus erythematosus, also cause transverse myelitis.

The spinal cord itself can sometimes become infected,

and a cord abscess may form.¹¹ The symptoms of cord infection are indistinguishable from those of an epidural abscess. Sources of cord infection include hematogenous spread, which is known to be a complication of congenital dermal sinuses, and bacterial endocarditis.

It has been suggested that the pathophysiology of cord infection is similar to that of cerebral infection. In the initial myelitis phase, cord edema and enlargement are observed. At approximately 1 week, a poorly defined ring of enhancement begins to appear. This results in the formation of an abscess cavity, which is relatively isointense on T1-weighted images and hyperintense on T2-weighted images. Cord abscesses are less well defined and less intensely enhancing than brain abscesses. This may be

Figure 25-7. Transverse myelitis. T2-weighted sagittal image through the cervical spine demonstrates the presence of increased signal in the dorsal columns of the spinal cord. This appearance is nonspecific and can be caused by a demyelinating process or infarction. In this instance, it was associated with a transient myelitis.

Figure 25-8. Meningeal infection, with subtle enhancement of the meninges covering the lumbar nerve roots. *A*, Post-contrast-enhanced T1-weighted image. The end of the conus medullaris at T12 is a flame-shaped structure that is slightly hypointense relative to the enhancing meninges and nerve roots. *B* and *C*, Axial contrast-enhanced images below the conus show that the nerve roots are thickened and enhancing. This nonspecific finding is compatible with meningitis and other disease processes.

because the cord is relatively hypovascular compared with the brain.

Bacterial abscess of the spinal cord has been thought to occur as a result of bacteremia.² Recently, cord abscesses have been reported in patients in whom the source of infection was not found.¹¹

Meningeal Infection

Many infectious agents gain access to the central nervous system by first infecting the meninges. When encountered on MR images, meningeal infections produce a vague and subtle enhancement of both the dura and the leptomeninges (Fig. 25–8). Like transverse myelitis, this is a nonspecific finding; it can be caused by trauma, recent lumbar puncture, and various vascular malformations. For detecting meningeal infection, analysis of the cerebrospinal fluid is much more sensitive and specific, and much cheaper to perform, than any imaging procedure.

Image-Guided Spinal Interventions

Wade H. Wong, Huy M. Do, Barton Lane

Spine Biopsies

Biopsies of the spine can play an important role in determining the correct diagnosis because imaging, although sensitive, is often nonspecific. When the patient may have an infection, a prompt biopsy can help the clinician define the organism and determine the optimal antibiotic sensitivity for early treatment. A spinal biopsy can provide a pathologic diagnosis that is critical to staging and treatment planning of neoplasms.

Image guidance for biopsies of the spine is commonly provided with fluoroscopy or computed tomography (CT) scanning. In unique situations, image guidance with magnetic resonance imaging (MRI) might be provided.

Fluoroscopy

Biopsies of the lumbar spine are readily and efficiently performed with fluoroscopic guidance. C-arm fluoroscopy is preferable to single-plane fluoroscopy because it allows the patient to remain in a stationary position while multiplanar relationships of the biopsy needle relative to the target are rapidly determined. The technique of fluoroscopic needle biopsy of the lower lumbar spine begins as follows. The patient is positioned *isocentrally* within the C-arm fluoroscope in such a way that the target area within the patient is centered in the rotational axis of the C-arm fluoroscope. This can be rapidly accomplished by first positioning the target in the lateral view and then adjusting its location so that it is centered on the anteroposterior view.

Most biopsies of the spine can be performed with local anesthesia, although conscious sedation is sometimes helpful. After the patient is prepared and draped, an anesthetic needle is used to anesthetize the skin with a rather generous wheal, so that if the point of entry must be moved, it can be done so without having to reanesthetize the skin. Leaving the anesthetic needle in the skin by detaching the syringe from the needle with the needle along the intended trajectory course saves time in subsequent needle placements. With the initial anesthetic needle serving as a relative directional marker both on images and on the skin, longer needles can subsequently be placed with positional readjustments as necessary, so that the final needle can be placed in tandem (or coaxial) fashion relative to the target zone.

Most biopsies of the lumbar spine (from about L2 to L5) can be performed from a posterior-lateral starting point, usually about 10 cm lateral to the spinous processes on an

average-sized adult. The view taken from this *posterior-lateral approach* is similar to that for a facet injection or for a diskogram (Fig. 26-1). Use of this approach permits a favorable trajectory to the center of the spine while avoiding the thecal sac if the operator should direct the needle too far posteriorly or avoiding the bowel or other internal abdominal viscera if the operator should direct the needle too far laterally.

Final needle placement is confirmed through visualization of the needle position on the anterior-posterior plane as well as on the lateral plane. This helps to confirm the needle position and depth.

An alternative to the posterior-lateral approach is the

Figure 26-1. Fluoroscopically guided biopsy of L3 vertebra from a posterior-lateral approach starting about 10 cm lateral to the spinous processes in an average-size patient. This approach provides a clear view of the articular facet joints and would be the same for a facet injection or for a lumbar diskogram. When the bone is entered, anterior and lateral views should be obtained to determine the correct depth of placement in the vertebra. An 11-gauge core biopsy needle was used, and the diagnosis was staphylococcal osteomyelitis.

Figure 26-2. Fluoroscopically guided needle biopsy of the L5-S1 disk using a curved needle from a posterior-lateral starting point. The needle was passed over the iliac crest and then down to the level of the L5-S1 disk, at which point the needle was rotated medially to enter the disk. This is the same technique that would be used for a diskogram at the L5-S1 level. The diagnosis was diskitis due to *Streptococcus viridans*.

transpedicular approach, in which the needle is passed through the pedicle. With this approach, the needle can be angled slightly superiorly or inferiorly but movement medially or laterally is somewhat limited. For the transpedicular approach, the operator should avoid entering too far medially or inferiorly on the pedicle as this runs the risk of injury to the nerve root either in the lateral recess or at the neural foramen.

Fluoroscopically guided biopsies of the inferior margin of L5, the L5-S1 intervertebral disk, and the superior margin of S1 may be difficult from a posterior-lateral approach unless a curved needle is used to pass the needle over the intervening iliac crest and then down into the target area (Fig. 26-2). This technique is similar to performing an L5-S1 diskogram from the posterior-lateral approach.⁵⁹

In all other areas of the spine, CT may be the preferred method of biopsy unless a transpedicular approach is taken with fluoroscopy.^{4, 44} In the upper lumbar and thoracic regions, CT provides a means of visualizing the adjacent lung and other posteriorly located visceral organs, such as the kidneys, in the case of a high lumbar target.

In the cervical region, CT may also be the preferred method of image guidance for biopsies because it can be used to define the positions of the jugular vein, carotid artery, vertebral artery, and pharyngeal and esophageal structures more accurately than fluoroscopy can (Fig. 26-

3). Furthermore, to perform cervical biopsies with fluoroscopy, the operator may have to place his or her fingers in such a way as to deviate the carotid sheath laterally and the pharyngeal structures medially. This still poses the risk of inadvertent perforation of the esophagus, pharynx, or one of the major blood vessels that have been fixed in position. In addition, fluoroscopically guided needle biopsies of the cervical spine may subject the operator's hands to radiation while the fingers are pressing between the carotid sheath and the pharynx/esophagus.

For paraspinal soft tissue biopsies, fluoroscopy is at a great disadvantage, compared with CT, in that it is difficult to visualize a paraspinal soft tissue target under fluoroscopy, whereas these areas become apparent under CT (Fig. 26-4).

If CT is chosen for image guidance for spine biopsy, the area of concern should first be localized with a scout film. We often place a V-shaped reference marker over the area of concern (see Fig. 26-3A). This marker consists of a polyethylene catheter that is bent at an acute angle and taped over the target zone. The marker helps to localize the level at which the optimal target will be found by providing a measurement of the distance between the limbs of the V, and we can confirm the location through localization with the laser light. From one of the limbs of the V marker on the patient, a starting point can be measured on the CT scanner and duplicated on the patient's skin surface.

We then prepare the patient. We use progressively longer anesthetic needles and deliver local anesthetic agent with a very large skin wheal. We leave the anesthetic needles in place, after they are disconnected from the syringe, along the anticipated trajectory for the biopsy needles. We scan and then readjust the trajectory of the anesthetic needles accordingly and place progressively longer anesthetic needles to the target, correcting the course trajectory as necessary. When we finally reach the periosteum along the optimal trajectory, we direct a bone biopsy needle into the bone and into the target zone, usually from a tandem technique. If a smaller bone biopsy needle is used (e.g., a 17-gauge needle), a larger coaxial guiding needle can be used for multiple passes.

The advantage of using a coaxial system is that the operator can easily perform multiple biopsies along an intended trajectory. The disadvantage is that most bone biopsy needles are quite large, often 13 and 11 gauge, and a considerably larger guiding needle is necessary for coaxial passage.

The advances of slip ring technology with a continuously rotating x-ray tube, x-ray tubes with improved heat capacity, more sensitive semiconductor detectors, new imaging reconstruction algorithms, and high-speed parallel-array processor systems for real-time raw data reconstruction and display allowed the eventual development of real-time CT fluoroscopy.¹¹ Helical CT scanners with CT fluoroscopy are widely available. Depending on the vendor, frame rates vary from two to eight frames per second, and the continuous CT fluoroscopy time varies from 40 to 100 seconds.

The main advantage of CT fluoroscopy guidance, compared with conventional CT guidance, is the decreased time needed for the procedure; the operator can see in real

Figure 26-3. CT-guided biopsy of the cervical spine.

A, Lateral scout view of the cervical spine with an overlying V-shaped polyethylene marker for reference (white arrows). Measurement of the distance between the V can help to confirm the location from which biopsy samples are to be taken and can provide a reference mark for measurement to the starting point.

B, The V-shaped catheter on this patient's skin surface is outlined (white arrows), and the level to be targeted is confirmed by matching the distance between the V-shaped catheter at this level with what is seen on the scout view. Black arrowheads denote the needle course taken posterior to the jugular vein and anterior to the vertebral artery.

C, Biopsy is performed with a lightweight 17-gauge EZEM bone biopsy needle under CT guidance along the intended trajectory course. This needle has no heavy handles to throw it off course if it is unsupported when directed under CT guidance.

time the movements of the biopsy needle (Figs. 26-5 and 26-6). The disadvantage is increased radiation exposure to the operator,^{11, 32, 33, 36} which should improve with the developments of special needle holders and even more sensitive semiconductor detectors, permitting improved image quality with lower milliamperere doses.^{11, 32, 33}

For CT needle guidance in the thoracic region, the usual trajectory is between the rib head and vertebral body (*costovertebral approach*). This approach avoids placement of the needle through the lung or through the exiting nerve root at the neural foramen. This technique usually allows

good angulation when other various zones of the vertebral body are targeted. The alternative approach to thoracic biopsies is a transpedicular approach, which provides limited medial or lateral angulation for targets throughout the vertebral body. A transpedicular approach can be used under either CT or fluoroscopic guidance (Fig. 26-7).

For cervical biopsies, most patients tolerate being on a side (lateral) position for longer periods of time than they would in a prone position, which often results in claustrophobia. The trajectory chosen should avoid the carotid sheath, pharynx, esophagus, vertebral artery, and spinal

Figure 26-4. CT-guided needle biopsy of a painful paraspinous muscle mass. This lesion could not be seen fluoroscopically, and CT guidance was therefore necessary. A 25-gauge needle easily yielded cytologic samples to make the diagnosis of a metastatic transitional cell carcinoma to the psoas muscle before the primary malignancy site was discovered.

Figure 26-5. Multiple images from noncontrast CT (A) and CT fluoroscopy (B and C) sequences during a biopsy of a mixed lytic and sclerotic lesion in T12 vertebra. These images demonstrate the successful biopsy of this small lesion (A) (arrows). Note that the needle angle trajectory avoids the left kidney, rib, and pedicle (arrows). The cytologic diagnosis was metastatic adenocarcinoma consistent with a breast origin.

Figure 26-6. Biopsy of a left paraspinal soft tissue mass. CT fluoroscopy images demonstrate advancement of biopsy needle with changes in needle orientation and depth from A to B (arrows). CT fluoroscopy allows the changes to be made in real time. The pathologic process was bacterial osteomyelitis.

Figure 26-7. CT-guided thoracic spine biopsy; two approaches are shown. One follows the posterior aspect of the rib down to the costovertebral junction (white arrow). If this approach cannot be easily made, an alternative approach is transpedicular (black arrow). The diagnosis was metastatic mucinous carcinoma of the colon.

contents. Sometimes it is very difficult to select a trajectory to avoid any of these structures. In some cases, a transpedicular trajectory may have to be taken. At other times, a stiff, large-bore needle can be placed behind the carotid sheath to shove the carotid sheath anteriorly, with the needle then redirected more posteriorly toward the target. From that point, coaxial biopsy needles can be passed through the larger guiding needle into the spinal target area.

Aspiration may be necessary for biopsy of soft tissue masses or abnormal fluid accumulations, whether present in soft tissues or bone. Aspiration techniques are often best performed with two operators using two sets of hands. One set of hands directs the needle into the target and performs the biopsy with forward and back rotary motions in the area of abnormality, usually with excursions of about 1 cm or less; the other set of hands provides suction via extension tubing from the needle to a large syringe (30 to 50 mL) with about 10 to 15 mL of suction pressure. The operator should be careful not to withdraw excessive amounts of blood because this action may interfere with the pathologist's diagnosis.

Biopsy of fluid-filled necrotic masses should also include the rim of the necrotic zone because the actual abnormal histology may be around the periphery, whereas the center may contain only necrotic debris. If the operator encounters a large paraspinal abscess, percutaneous drainage of the abscess at the time of biopsy by additionally placing a large-bore (10 French) catheter either with the Seldinger technique or with a single-pass trocar system (e.g., Cope). This can provide a large-volume specimen as well as a way to initiate therapy by draining the abscess.

Before performing a biopsy on lesions that are suspected to be caused by infection, the operator should ask the referring physician whether the patient has been taking antibiotics, which can interfere with organ growth and yield false-negative results. Ideally, any lesion that is thought to be due to infection should immediately undergo biopsy well before antibiotics are started. If antibiotics have already been started, they may have to be discontinued for 1 week to 10 days before the biopsy to ensure adequate growth of the organisms for positive results.

We generally request that a pathologist be available at the time of the biopsy to confirm whether an adequate sample has been taken. If the pathologist cannot make an initial diagnosis, further specimens may be necessary. Sometimes excessive blood in the specimen interferes with the pathologist's ability to make a clear diagnosis. If a specimen of paraspinal soft tissue lesions is obtained for biopsy and considerable blood is found in the specimen, sometimes a very thin (e.g., 25-gauge) needle without aspiration (instead of a larger-bore needle) may yield positive cytology. On the other hand, a spring-loaded cutting core biopsy needle (e.g., Cook, Temno) might be considered to slice free a portion of the target without the aspiration of a great deal of blood.

If the operator suspects that the lesion is an extremely vascular mass, such as a renal cell carcinoma with metastasis to the spine, a spinal angiogram may have to be obtained. If the angiogram confirms the vascular nature of the lesion, spinal embolization, via either arterial access or direct puncture of the lesion with the injection of either absorbable gelatin powder (Gelfoam, Gel-O-Foam) or polyvinyl alcohol particles, may be necessary before sam-

ples of the lesion are taken. This measure may help to prevent serious hemorrhage.

Needles

A variety of needles can be used for biopsy of the spine and paraspinal soft tissues.

Thin-Walled Needles

20- and 22-Gauge Needles

Straight, thin-walled needles (e.g., 20- and 22-gauge Chiba-type) can be used to aspirate abscesses, disks, soft tissues, or abnormally lytic bone lesions. Because 20-gauge needles are somewhat stouter than 22-gauge needles, directional control is more easily accomplished with 20-gauge needles, particularly if a complex curved trajectory must be used. The 20-gauge needle does not produce quite as much trauma as that from the 18-gauge needle and is usually sufficiently stout to penetrate a thin shell of bone in the presence of a lytic bone lesion.

25-Gauge Needles

The 25-gauge needle is often used in biopsies of very vascular soft tissue masses in the paraspinal areas and have the advantage of limiting the blood loss.

Core Biopsy Needles

Spring-loaded core biopsy needles (e.g., Temno or Cook) may be necessary for paraspinal soft tissue masses that are quite fibrous or reluctant to give up cells during fine-needle aspiration. Because lymphomas, schwannomas, and certain other fibrous tumors are often resistant to fine-needle aspiration, the use of a cutting type of needle (e.g., a spring-loaded core biopsy needle) may be necessary to obtain an adequate sample. With core biopsy needles, it can be difficult to maintain direction because of the weight of the handle when they are used under CT guidance. It may be best to direct the cutting needle through a coaxial guiding needle, which can be placed precisely under CT guidance, and avoid the problem of handle weight of the core biopsy needle.

Bone Biopsy Needles

A variety of bone biopsy needles are available, ranging from sharp-threaded, drilling-type 17-gauge needles (e.g., EZEM) to large-bore 11-gauge needles (e.g., Mannon, Cook). For sclerotic or blastic bone lesions of the spine, the more specimen that is collected, usually the better it is for the pathologist, because these lesions are often difficult to adequately decalcify for diagnosis. Therefore, for sclerotic bone lesions, bone biopsy needles of 11 gauge or larger are usually best.

When a spinal lesion is in a place that is difficult to access (e.g., a tight passage between the carotid sheath and vertebral artery in the upper cervical spine), lightweight short drilling needles, such as the 17-gauge EZEM, may be advantageous in setting and keeping trajectories in shallow soft tissues, in contrast to larger 11-gauge needles with heavy handles, which often throw the trajectory of the needle off course when used under CT guidance. Because

the small 17-gauge EZEM needles are short and very lightweight, they can be set in shallow soft tissues during targeting and still hold their trajectory without hand support. Because they are also very sharp and are threaded, they can thus be drilled deeply into the bone to obtain core samples very effectively in most cases.

General Precautions

Before biopsy, the operator should check for coagulopathies (bleeding time, prothrombin time, partial thromboplastin time, platelets). For coagulopathic patients or patients receiving anticoagulants, the procedure may have to be postponed.

When biopsies are performed on thoracic lesions, the operator should always be cautious of a possible pneumothorax; at termination of the procedure, either a follow-up set of CT scans through the lungs with lung windows or an expiratory chest x-ray film should be obtained to rule out a pneumothorax. A chest tube kit should be obtained or arrangements for the placement of a chest tube made before biopsy of the thoracic spine.

When pushing or drilling a needle through very dense bone, and when vital structures such as the aorta, the carotid artery, or the vertebral artery are located just beyond the target zone along the trajectory path, the operator may want to use a détente technique with one hand pushing the needle toward the target and the other hand grasping the needle shaft to provide a counteraction force, if necessary, to prevent piercing beyond the target area into vital structures if resistance to the needle should suddenly give way.

The operator should also be cautious when delivering the sample to the pathologist. It is wise to have a pathology team available to accept the specimens to avoid embarrassing misplacement. When delivering a bone core that may be impacted within the bone biopsy needle, it is prudent to avoid pushing the core out of the needle with such force that it suddenly flies off the slide and becomes lost. To remove a bone core from the biopsy needle, the operator should use the appropriate trocar design that is intended for such removal.

MRI-Guided Spinal Biopsies

Increasingly, MRI is being used for guidance and control of minimally invasive percutaneous and surgical procedures. Technologic advances such as the introduction of open and short-bore magnet designs, the proliferation of fast imaging sequences, and the availability of MRI-compatible instruments have aided the growth of this field.³⁶ We discuss the role of interventional MRI as it pertains to percutaneous spinal biopsies. For readers interested in MRI guidance related to neurosurgical procedures, potential percutaneous vascular applications, laser therapy, radiofrequency ablation, and biopsy of other parts of the body, more detailed works are recommended.*

The best design of an MRI system with regard to high-quality images and low field inhomogeneity would be a spherical magnet.²³ However, this design presents a subop-

timal environment for MRI-guided intervention, which requires free access to the patient. Early reports of MRI-guided biopsies and aspirations were made with conventional cylindric superconducting systems.⁴² This technique is similar to CT-guided procedures, in which access to the patient is limited and the patient must be withdrawn from the magnet for the manipulation of biopsy equipment, resulting in relatively long procedure times.

Three types of magnets are used clinically for MRI-guided therapy:

1. Closed, short-bore cylindrical superconducting systems operating at between 1.0 and 1.5 tesla (T).
2. Open, midfield ("double-donut") systems operating at 0.5 T.
3. Open, low-field (biplanar) systems operating at between 0.064 and 0.3 T.

The improvement in access to the patient that is afforded by the open magnets is traded for decreased field strength and image quality.^{36, 54}

The main advantage of closed magnets, operating at high field strengths, is superior image quality relative to static magnetic field strengths and homogeneity. Also, the excellent signal-to-noise ratio achieved with these systems is well suited for temperature monitoring and mapping during ablative therapy with laser or radiofrequency.^{1, 2, 23, 24, 36, 42} The disadvantages of this type of magnet design are the limited access to the patient and the relatively longer procedure times.

MRI-compatible accessories are available from several manufacturers. As with other cross-sectional imaging-guided modalities, such as CT and ultrasonography, the correct needle choice depends on whether tissue is required for cytologic or histologic analysis. Fine-aspiration, side-cutting, and bone biopsy needles are available in sizes ranging from 14 to 24 gauge. To achieve minimal artifact and no torque in the magnetic field, needles are composed of nonferromagnetic metals such as titanium, tantalum, and tungsten with aluminum or vanadium alloy.⁴³

The main disadvantage of these needles is their relative bluntness and softness compared with stainless steel needles. Thus, in the case of intact cortical bone or sclerotic bony lesions, the biopsy procedure may be technically difficult and time-consuming and the patient may experience some discomfort. MRI-compatible bone drill systems are being developed to overcome this somewhat vexing problem.⁴³

Factors such as lesion conspicuousness, needle passive image artifacts, and image contrast between the lesion and the instruments must be considered in an MRI-guided procedure. The instrumentation-based image artifacts depend mainly on the following^{1, 37, 57}:

- Needle size
- Orientation of the needle to B_0
- The field strength B_0
- The imaging sequence parameters used for the procedure

The greater the angle of the needle to B_0 , the more conspicuous is the artifact size, with maximum visibility at 90 degrees. The artifact becomes larger with increasing MRI field strength. Put simply, gradient-echo sequences are more sensitive to local field inhomogeneities and intravoxel

*See references 1, 2, 7, 24, 30, 31, 34, 39, 48, and 51 to 54.

dephasing than spin-echo sequences are. Therefore, techniques such as T2-weighted fast spin-echo sequences produce smaller artifacts than those noted with gradient-echo scans. The physical basis of these phenomena is beyond the scope of this discussion and has been well described in the literature.^{1, 16, 36-38} Effective clinical application of MRI-guided procedures requires consideration of these different factors and appropriate adaptation.

Indications for percutaneous biopsy of the spine include cytologic or histologic analysis and diagnosis of soft tissue or bone lesions of unknown etiology. MRI is an alternative to CT and ultrasound in imaging guidance; MRI's multipla-

nar imaging capability probably is the most advantageous feature of this modality when compared with the other two modalities. This feature is important in planning needle trajectories in which the operator would want to avoid vascular structures (e.g., in head and neck biopsies) or in other important tissue planes (e.g., interposed bowel or the diaphragm). Occasionally, MRI can be used to visualize lesions that are either invisible or poorly seen on CT scans or sonograms. The superior soft tissue contrast and spatial resolution that MRI affords are most dramatic in the setting of bone marrow changes of unknown etiology, which are often invisible with CT (Fig. 26-8). An MRI-guided proce-

Figure 26-8. Bone marrow changes of unknown etiology. This potential abnormality was not visible on CT. A, Sagittal T1-weighted localizer image demonstrates patchy infiltration of the bone marrow in multiple lumbar vertebral bodies (arrows). B-D, Real-time axial images during left L5 transpediculate biopsy. Note susceptibility artifacts from needle. Cytologic diagnosis was negative for malignancy.

ture is also advantageous when radiation exposure is a consideration, as in younger patients, or when a patient has a history of allergy to an iodinated contrast agent.

MRI-guided biopsies of soft tissue and bony lesions of the spine appear to be safe and effective. There are obvious limitations to this technique, such as smaller lesions, which may be obscured by needle artifacts. Patient size and weight may also be limiting factors. Early results of MRI-guided biopsies seem to be as accurate as those of CT-guided techniques.^{28, 43} MRI-guided techniques (not only biopsy and aspiration but also intraoperative monitoring and therapeutic procedures) are under constant evaluation and evolution and will probably become important tools in the armamentarium of radiology.

Diagnostic and Therapeutic Spine Interventions

Diskography

Indications

Diskography is commonly performed when imaging results are confusing or inconclusive. Sometimes the images may reveal more levels of abnormality than would be suspected on the basis of the clinical examination. At other times, images may fail to reveal any apparent abnormalities when the clinical examination strongly suggests a diskogenic etiology.⁵⁰ Shellhas and colleagues⁴⁹ reported that diskography could be extremely beneficial when MRI findings were negative. Colhoun and associates⁸ noted that of 137 patients with positive diskographic findings, 89% derived significant sustained clinical benefit from subsequent surgery.

Diskography may also be used in the evaluation of postsurgical diskogenic pain and of presurgical fusion when disk disease is suspected in relation to underlying spinal instability.²² Diskography is also indicated for the diagnosis of disk disease before percutaneous discectomy or intradiscal electrolytic therapy.

Technique

The diskogram is a provocative test that is based on reproduction of the patient's original pain as a result of an increase in intradiskal pressure caused by the injection of fluid into the disk. This fluid is usually intrathecal compatible iodine contrast medium (e.g., Omnipaque 180), and the pressure increase is usually accomplished by injecting 1 to 1.5 mL into a lumbar disk or about 0.5 mL into a cervical disk. Because of the risk of infection, many operators add a broad-spectrum antibiotic to the iodine contrast mixture (e.g., cefazolin at about 50 mg per 1 mL of iodinated contrast medium).⁴⁹

For lumbar diskography, a posterior-lateral approach is usually taken under fluoroscopic guidance. The most common disks to be injected in the lumbar region are L3-4, L4-5, and L5-S1.

Straight needle trajectories can usually be taken for the L3-4 and L4-5 disks (Fig. 26-9); however, because the iliac crest blocks a direct trajectory to the L5-S1 disk, a curved trajectory of the needle must be taken for the L5-

Figure 26-9. Anteroposterior view of contrast medium injected into the L3-4 disk following a posterior-lateral approach for needle placement under fluoroscopic guidance. Injection of contrast medium demonstrates a bifid configuration of medium in a normal-appearing disk. However, the patient complained of marked pain reproduction on injection into this disk.

S1 disk. The operator passes a curved needle superiorly over the iliac crest from a posterior-lateral starting point, then inferiorly to the level of the disk, and then medially into the disk (see Fig. 26-2). A C-arm fluoroscope is definitely advantageous for this complex trajectory. Some operators use CT scanning, which may be appropriate for L3-4 and L4-5 diskography, but the orientation of the L5-S1 disk makes access with CT guidance difficult unless a transthecal approach is used. For thoracic and cervical diskography, CT guidance may be preferred to fluoroscopic guidance, similar to image-guided biopsies (Fig. 26-10). Some operators prefer to perform cervical diskography with fluoroscopic guidance, in which case they deviate the carotid sheath laterally and then deviate the pharynx/esophagus medially with the fingers of one hand and then with the other hand pass a very thin (25-gauge) needle into the disk.

After diskography, a CT scan of the disk containing injected contrast medium can be performed to obtain additional information. Sometimes this secondary information reveals other corroborative evidence of disk disease, such as an annular tear (Fig. 26-11).

Complications

The frequency of complications following diskography has been reported to be as high as 3% by Fraser and associates,¹⁷ but the general overall rate is less than

Figure 26-10. Cervical diskography at the C5-6 level performed with CT guidance using a 25-gauge needle via an anterior-lateral approach. The patient's right arm pain was reproduced exactly on injection of 0.5 mL of iodine contrast medium. After injection, the CT scan also demonstrates a small amount of contrast medium filling a right posterior-lateral disk protrusion (arrowhead).

0.15%.²² Complications can include infection, bleeding, nerve injury, chemical diskitis,⁵⁰ hypotension (vagal), pneumothorax, and cerebrospinal fluid leak leading to spinal headaches.

Initial Spine Interventions: Epidural Steroid Injections versus Joint Injections

The most common spinal interventional procedures that may be both diagnostic and therapeutic include epidural

steroid injections and joint injections (facet and sacroiliac joint injections). Often, these injections represent the initial diagnostic spine interventions that lead to more definitive therapy.

The evaluation of back pain starts with a history and physical examination, and findings are correlated with the imaging study. If the pain is *radicular* in nature, the operator may start with an epidural steroid injection. If the patient benefits from this injection, a subsequent epidural steroid injection can be administered about 4 weeks later, leading to another epidural steroid injection in about 4 weeks if there is continued positive benefit. At that point, maintenance epidural steroid injections at about 2- to 3-month intervals can be administered for continued pain relief.

If at any time the patient does not experience a positive benefit, he or she should be reevaluated. If the pain instead seems to be more focal, a joint injection may be considered.

If relief does not result after the epidural steroid injections, the patient should be considered for a surgical evaluation or referred for treatment with oral medications (narcotics, nonsteroidal anti-inflammatory drugs).

If on initial evaluation the patient's pain seems to be more *focal* (i.e., over a facet or sacroiliac joint), a joint injection might be given first. If there is positive benefit, another joint injection can be administered in 4 weeks; again, if there is positive benefit, a subsequent joint injection can be administered in 4 weeks.

If there continues to be positive benefit, maintenance joint injections can be considered for long-term therapy at 2- to 3-month intervals. If the patient does not receive positive benefit from the initial three joint injections, he or she should be reevaluated.

If the pain pattern seems to be more *radicular* than *focal*, epidural steroid injections should be considered. Otherwise, the patient may be a candidate for either surgical or medical referral.

Epidural Steroid Injections

Epidural steroid injections are commonly administered when the patient is experiencing radicular symptoms, often

Figure 26-11. Postdiskography CT scan reveals contrast medium in the L5-S1 disk filling a small central disk protrusion. Although the CT scan appears to be abnormal, indicating an annular tear, the patient was totally asymptomatic. Thus, disk protrusion would be considered only an incidental finding at diskography.

due to spinal stenosis, which may be a result of generalized degenerative changes, disk disease, or facet arthrosis. Postsurgical scarring may also be an indication for epidural steroid injections. If an exact cause of pain is not clearly discerned, an epidural steroid injection may sometimes be the first injection procedure attempted to alleviate pain.^{5, 14}

Injection at Lumbar Sites

For low lumbar disease, the operator can administer a caudal injection.⁴⁵ The operator palpates an indentation along the lowest portion of the sacrum and, under fluoroscopic guidance, inserts a needle into the sacral hiatus. Caution is needed to prevent inadvertent placement of the needle anterior to the sacrum (into the rectum) or posterior to the sacrum (into the posterior sacral soft tissues). The needle should not be directed superiorly to S3 because a low-lying thecal sac might be encountered.

Iodine contrast medium is injected (~2 mL iohexol [46.36% iodine; Omnipaque 180]) to confirm optimal placement in the sacral epidural space and not into the thecal sac. A long-acting steroid (18 mg betamethasone [Celestone]) is then usually injected.

For other sites of the lumbar spine, from about L3 superior into the cervical region, the operator places an epidural needle such as a Tuohy, which has a somewhat curved blunted tip, into the epidural space, as with a myelographic approach (either midline between the spinous processes or paramedian). C-arm fluoroscopy is usually the preferred imaging modality.

Needle Placement

Two techniques are commonly deployed for placing the epidural needle in the correct location.

1. *Direct saline pressure method.* A glass syringe with saline is connected to the end of the epidural needle, and intermittent pressure is applied as the needle is directed to the epidural space under fluoroscopic guidance. On reaching the epidural space, there typically is a remarkable loss of resistance such that the plunger is easily pushed forward with very little resistance.
2. *Hanging drop method.* A drop of saline is placed over the posterior hole of the Tuohy needle, which is then guided by fluoroscopy down to the epidural space. The blunt tip of the Tuohy needle tends to depress the rather tough dura, creating a vacuum effect, and this sucks the drop of saline inward to signify that the needle has reached the epidural space. The operator confirms needle tip location by performing an epidurogram. This is easily accomplished with an injection of about 2 mL of intrathecally compatible iodine contrast (Omnipaque 180).

At fluoroscopic examination, the anteroposterior view should reveal a streaky contrast medium collection that may extend out through the nerve root sleeves; the lateral view may show a linear collection of contrast medium adjacent to the expected location of the thecal sac (Figs. 26-12 and 26-13). If the needle penetrates the thecal sac, the injection of steroids, and especially a local anesthetic agent, should be avoided. The injection procedure can be postponed for 1 week to allow the hole in the thecal sac to

Figure 26-12. Lumbar epidural steroid injection. The lateral view demonstrating the linear accumulation of contrast medium along the posterior aspect of the lumbar epidural space. There is no intrathecal contrast filling. This epidurogram confirms optimal needle placement.

heal, or the epidural steroid injection can be administered at a different but adjacent level.

A study by Johnson and colleagues²⁷ that involved 5334 patients showed that the efficacy of epidural steroid injections with fluoroscopically guided needle placement and confirmatory epidurography was extremely high (97%) and the complication rate was very low (0.07%). This is in contrast to *blind* epidural steroid injections, as commonly performed by anesthesiologists, who experience up to a 30% rate of inaccurate needle placement.

Facet Injections

Facet disease can cause focal pain or referred local pain.^{3, 18, 41} Median branch nerves from the nerve roots above and below the facet joints supply the innervation to the facet joints.⁶ The injection into a facet joint under fluoroscopic guidance is not usually difficult unless there is considerable hypertrophic degenerative spurring, which may alter the choice of entry point into the facet joint. In those cases, targeting by CT guidance may be preferred.

On the needle's entry into a facet joint, the operator injects a very small amount of iodinated contrast agent (0.1 to 0.2 mL of Omnipaque 180) to confirm needle tip location within the facet joint. The operator should visualize a linear contrast medium accumulation in the facet joint or filling of the recesses (or both) that appears as bulbous collections of contrast medium along the superior and inferior margins of the facet joint (Fig. 26-14). A local anesthetic agent (lidocaine) can be injected for diagnostic purposes, whereas an injection of a long-acting anesthetic agent and a long-acting steroid (0.5 mL of a 50:50 mixture of 0.25% bupivacaine [0.25% Marcaine] and 6 mg/mL betamethasone) is administered. In the cervical region, a fluoroscopically guided lateral approach is usually taken (Fig. 26-15) except for the C1-2 facet joint, which is composed of the lateral masses of C1 and C2. CT guidance

Figure 26–13. Cervical epidural steroid injection showing a linear contrast accumulation in the posterior cervical epidural space. No intrathecal contrast medium accumulation is seen. This epidurogram confirms optimal needle placement.

Figure 26–14. Lumbar facet injection under CT guidance. Initial attempts were performed under fluoroscopic guidance, but the visualized trajectory to the facet joint (arrowheads) was blocked by the posterior-superior articular facet osteophyte. Therefore, CT guidance was used to reveal the true posterior entry point into the joint. Most facet injections can be performed rapidly with fluoroscopic guidance, but the more difficult ones, such as this one, should be reserved for CT guidance.

Figure 26–15. Lateral view of the cervical spine showing correct needle placement for C3-4 articular facet joint injection. The operator should not approach the joint too far anteriorly to avoid puncture of the vertebral artery. Contrast medium in the joint shows a normal linear accumulation along the joint margins, which confirms correct needle placement.

Figure 26-16. C1-2 articular facet joint injection. A, Anteroposterior view. Plain film of the C1-2 facet joints demonstrates that the normal facet joint (arrows) is made up of the lateral masses, whereas the abnormal right-sided facet joint (arrowheads) is extremely sclerosed. B, Injection of the right C1-2 facet joint with CT guidance from a posterior-lateral approach that avoids the vertebral artery (arrowhead), with the needle well positioned in the C1-2 facet joint.

may be preferred to fluoroscopic guidance to avoid injury to the vertebral artery or the C1 and C2 nerve roots during injection into the C1-2 facet joint (Fig. 26-16).

An alternative to injection into the facet joints may be achieved by blocking the median branch nerves, which pass over the superior medial boundaries of the transverse processes arising above and below the level of the facet joint. This is known as a *median branch block*. If this procedure is effective in relieving pain, radiofrequency ablation of the median branch nerves may be considered for longer pain relief.¹³

As in the facet joints, pain emanating from the sacroiliac joints is typically focal, locally referred, or both. The sacroiliac joint injection is commonly made under fluoroscopic guidance. Placing the fluoroscope or the patient at an oblique angle until the joint margins are optimally seen may reveal the correct trajectory for the needle. However, overlap of the ilium and sacrum often presents problems for straight needle passage into the joint. Therefore, in some cases injection with CT guidance may be preferred (Fig. 26-17).

The sacroiliac joint is a diarthrodial joint in which the lower half is the synovial portion and thus the target area. When fluoroscopy is chosen, the optimal site for placement of a needle into the synovial portion of the sacroiliac joint is usually along the most inferior margin, which tends to have less bony overlap of the ilium on the sacrum (Fig. 26-18). Injection of iodinated contrast medium (~1 mL of Omnipaque 180) confirms correct needle placement, as defined by a linear streak of contrast medium in the joint. The operator can then inject about 3 mL of 1% lidocaine for diagnostic purposes or the same amount of a 50:50 mixture of a long-acting anesthetic agent (0.25% bupivacaine) and steroid (6 mg/mL betamethasone) for therapeutic purposes.

The complication rate following joint injection (facet and sacroiliac joints) with the use of thin 22- or 25-gauge

Figure 26-17. Bilateral sacroiliac joint injections with CT guidance. The left side of the sacroiliac joint was difficult to approach fluoroscopically. Arrowheads indicate the apparent approach to the left sacroiliac joint under fluoroscopy, but the iliac bone blocks access to this joint, which is somewhat curved. The right joint has a straighter trajectory and was able to be accessed with fluoroscopy. Nevertheless, CT provides the most accurate way of defining the opening to the sacroiliac joints. In this case, the true opening to the right side of joint was situated much more medially than was apparent under fluoroscopy.

Figure 26-18. Fluoroscopically guided sacroiliac joint injection. A 25-gauge needle was placed along the most inferior margin of the right sacroiliac joint. This inferior position tends to have less bony overlap of the ilium on the sacrum than when the joint is approached from a more superior position. Iodine contrast medium has been injected and is collecting along the joint margins (*arrowheads*), confirming correct needle placement.

needles is extremely low. Nevertheless, general precautions regarding coagulopathies, infections, allergic reactions, and hypotensive (vagal) events should always be considered.

Nerve Root Blocks

Nerve root blocks can be helpful diagnostically when the imaging findings are rather confusing. When multiple abnormalities are seen on an image, the blockade of pain related to a specific nerve root may specify the clinically relevant abnormality. Nerve root blocks may also be helpful therapeutically when there is irritation of a nerve root or when a patient is having radicular pain but is not a reasonable surgical candidate. Nerve root blocks can be achieved through injection into the ganglion at the neuroforamen,⁶¹ but the operator must be cautious to avoid communication with the subarachnoid space if a particularly long nerve root sleeve is present.

Careful scrutiny during injection of iodine contrast medium is necessary to rule out intrathecal communication. Alternatively, the operator can inject into the nerve roots along the postganglionic segment.

Lumbar Nerve Root Injections

In the lumbar region, the operator would insert a needle just over the superior margin of the midsection of the subjacent (lower) transverse process and probe gently with a 25-gauge needle until there is a paresthesia to the lower extremity. The operator then backs the needle off very slightly and injects iodine contrast medium, which should outline the nerve root sheath, with the nerve root being seen as a linear filling defect (Fig. 26-19). At that point, the operator can inject 1 to 2 mL of 1% lidocaine for diagnostic purposes or, for more permanent therapeutic pain relief, 1 to 2 mL of a 50:50 mixture of 0.25% bupivacaine and a long-acting steroid (6 mg/mL betamethasone).

Thoracic Nerve Root Injections

In the thoracic region, the postganglionic nerve roots can be located just under the inferior margin of the rib. For

thoracic nerve root blocks, the operator should be extremely cautious of needle depth to avoid a pneumothorax. Nerve root blocks can readily be accomplished under fluoroscopy.

Figure 26-19. Left L5 nerve root block, postganglionic segment. A needle is directed into the ganglionic portion of the nerve root at the neural foramen or along the postganglionic portion of the nerve root. To find the postganglionic portion of a lumbar nerve root, the operator passes a needle deeply from approximately the midsection of the lower transverse process or, in this case, the equivalent midsection of the sacral wing. Gentle probing is performed until the patient acknowledges an electric shock down the lower extremity. The needle is withdrawn just slightly, and iodine contrast medium is injected along the nerve sheath. Contrast medium can be seen tracking along the nerve sheath back toward the neural foramen. Injection of lidocaine can be administered for diagnostic purposes, and injection of bupivacaine and long-acting steroid can be administered for more therapeutic measures.

Cervical Nerve Root Injections

In the cervical region, the operator may prefer CT guidance to avoid the pharynx/esophagus and carotid sheath or vertebral artery, although some operators prefer to use fluoroscopic guidance for cervical nerve root blocks, similar to the technique of cervical diskography. To avoid the vertebral artery, the operator should place the needle in the posterior neuroforamen.

Trigger-Point Injections

Local soft tissue injections of an anesthetic agent, steroids, or both may be helpful when the patient has myofascial pain, perhaps due to scarring, myofascial strain, or strain related to ununited bone fusion. Targeted areas to be injected are based on subjective responses of the patient to soft tissue tenderness. These injections may help bring about relief and allow time for healing to occur (Fig. 26–20). For diagnostic pain relief in the soft tissues, 1 to 4 mL of 1% lidocaine may be injected, whereas a similar amount of long-acting anesthetic agent and steroid can be injected for longer therapeutic relief (e.g., bupivacaine, 0.25%, and betamethasone, 6 mg/mL).

Sympathetic Ganglion Blockade

Deep visceral pain may cause considerable referred pain from visceral somatic reflex arcs, which may worsen pain cycles. Sympathetic nerve blocks may help to decrease pain by breaking up reflex arcs. The common sympathetic ganglion blocks include:

1. *Stellate ganglion block* for upper extremity and lower facial and neck pain.
2. *Celiac ganglion block* for pain of the upper abdomen.
3. *Lumbar sympathetic block* for pain related to the lower extremities.

4. *Impar ganglion block* for pain in the lower pelvis and perineal regions.

Stellate Ganglion Block

Indications for blockade of the stellate ganglion include pain in the upper arm due to arterial insufficiency, Raynaud's phenomenon, reflex sympathetic dystrophy, post-traumatic syndrome with swelling, hyperhidrosis, and cyanosis, Pancoast tumors of the upper thorax, and herpes zoster of the neck and head.

Stellate ganglion blockade is accomplished under either fluoroscopic or CT guidance by directing a thin (25-gauge) needle to the stellate ganglion located at the anterior-lateral aspect of the C7 vertebral body and the junction with its transverse process (Fig. 26–21).¹⁵ The syringe attached to the end of the needle should be aspirated to be sure that the tip of the needle is not in a blood vessel—especially the vertebral artery. Injection of iodinated contrast medium further substantiates the location of the stellate ganglion and the absence of any intravascular filling.

For temporary pain relief, 0.25% bupivacaine (8 mL) can be injected on a weekly basis (usually up to 8 weeks). For pain ablation, 8 mL of absolute alcohol or 6% phenol can be used for neurolysis, preferably with the patient under general anesthesia, because the injection of absolute alcohol can be extremely painful. When effective stellate ganglion blockade is achieved, Horner syndrome develops and there may be venous engorgement and paresis of the ipsilateral face and arm.

The risks and complications of stellate ganglion blockade include the following:

- Intraplasmal extension of the medication (particularly if a long nerve root sleeve is encountered, which may lead to paralysis or even seizures)
- Intravascular injection

Figure 26–20. Trigger-point local soft tissue injections. The patient complained of considerable soft tissue tenderness in an area that was related to soft tissue strain adjacent to an ununited bone fusion. Weekly injections of 0.25% bupivacaine (6 mL) provided enormous pain relief for the patient until soft tissue healing was adequate.

Figure 26–21. Stellate ganglion blockade. Fluoroscopic guidance was used to place a 25-gauge needle along the lateral margin of the C7 vertebra and junction with the transverse process. Iodine contrast medium was injected (*arrow*) and revealed no evidence of intravascular contrast accumulation. Next, 8 mL of 0.25% bupivacaine was injected slowly.

- Paralysis of an adjacent phrenic nerve or a recurrent laryngeal nerve (which may lead to hoarseness or even diaphragmatic paralysis)
- Pneumothorax
- Hypotension with bradycardia (accelerator nerves through the heart also pass through the stellate ganglion)

Relative contraindications include:

- Recent myocardial infarction, because the patient may not be able to elevate the heart rate in cases of stress due to blockage of the accelerator nerves to the heart
- Coagulopathy
- Contralateral pneumothorax
- Glaucoma

Celiac Ganglion Block

Celiac sympathetic plexus blockades can be extremely helpful when the patient has deep visceral pain, as commonly occurs from terminal pancreatic cancer, chronic pancreatitis, or visceral arterial insufficiency. The operator places a thin needle from either a posterior or an anterior approach into the celiac, which is located just anterior to the aorta and surrounding the celiac artery.⁵⁵ CT guidance is often preferred, although ultrasound guidance with an anterior approach through the liver has been favored by some operators.²⁶

For a posterior approach with CT guidance, the operator starts by locating the celiac artery by scanning it at approximately the T12 level. A needle is directed from a posterior paraspinal location through the crura of the diaphragms in order to pass the needle anterior to the aorta at the level of the celiac artery (Fig. 26–22). The operator may need to pass a needle directly through the aorta to reach the target zone. Iodine contrast medium is injected to confirm needle location and the absence of intravascular communication. Temporary blockade is achieved when the operator injects bupivacaine; for permanent ablation, neurolysis can be obtained by an injection of absolute alcohol or 6% phenol.

Successful celiac blockade is usually accompanied by hypotension because blood tends to pool in the visceral circulation. This is usually treated effectively with additional intravenous fluids.

Relative contraindications to celiac ganglion blockade include bowel obstruction (because there may be an increase in motility resulting from obliteration of sympathetic input) and coagulopathy.

Figure 26–22. Celiac sympathetic plexus blockade from a posterior approach with CT guidance. Needles have been placed just posterior to the crura of the diaphragms at the T12 level. The needles are placed very close to the T12 vertebra and are directed in such a manner that the tips of the needles pass just anterior to the aorta. The celiac plexus is located at either side of the celiac artery. Iodine contrast medium confirms needle tip locations before the injection of absolute alcohol for celiac plexus ablation in a patient with severe upper abdominal pain from terminal pancreatic malignancy.

Lumbar Sympathetic Block

Blockade of the lumbar sympathetic plexus may be helpful in cases of lower extremity reflex sympathetic dystrophy, ischemia from chronic arterial emboli or Raynaud's phenomenon, phantom limb pain resulting from amputation, frostbite of the lower extremities, and hyperhidrosis of the lower extremities. The lumbar sympathetic plexus extends from approximately L5 to L2. Blockade is most effectively achieved when the operator directs a needle under either fluoroscopic or CT guidance to the anterior-lateral aspect of the L2 vertebra.²⁰ A posterior-anterior approach slightly off midline is usually taken.

Injection of iodine contrast medium confirms the absence of intravascular communication in either the aorta or inferior vena cava and that the needle is positioned retroperitoneally (Fig. 26–23). Temporary relief can be obtained by injection of about 10 mL of 0.5% bupivacaine on a weekly basis during a period of up to 6 to 8 weeks to break visceral somatic reflex pain cycles.

Complications may include inadvertent injections, neuralgia to the genital femoral nerve, urethral injury, hypotension, impotence, and bleeding.

Impar Ganglion Block

Blockade of the impar ganglion may be helpful when the patient has deep lower pelvic pain, pain from the perineum, or presacral pain. The operator places a thin, 22-gauge needle from a starting point between the sacrum and coccyx through the sacral coccygeal ligament and then directs it superiorly and posteriorly to the anterior surface

Figure 26–23. Lumbar sympathetic blockade. Fluoroscopic guidance of a 22-gauge needle from a slightly posterior-lateral approach to the anterior-lateral aspect of the L2 vertebra. Contrast medium is injected, showing retroperitoneal dispersion and the lack of intravascular communication. Then 10 mL of 0.25% bupivacaine was injected at weekly intervals for 6 weeks to ameliorate the patient's pain from reflex sympathetic dystrophy.

Figure 26–24. Fluoroscopic guidance of a double-curved needle in which the tip is placed just anterior to the sacrum. Iodine contrast medium reveals good dispersion without filling of the rectum. Absolute alcohol was injected for ablation of the impar ganglion in a patient with severe perineal pain from a malignancy.

of the sacrum. Iodine contrast medium is injected to ensure that the rectum has not been violated (Fig. 26–24).

For temporary pain relief, a long-acting anesthetic agent such as bupivacaine can be injected. For more permanent pain relief, absolute alcohol or 6% phenol can be injected, preferably with the patient under local anesthesia.

Vertebroplasty and Balloon Kyphoplasty: Novel Treatments of Painful Osteoporotic and Other Vertebral Compression Fractures

In the United States, there are more than 35 million cases of osteoporosis, of which 1.5 million result in fragility fractures. Seven hundred thousand of these fragility fractures affect the spine, and 200,000 of these fragility fractures of the spine are refractory to nonoperative care, resulting in frustratingly continued debilitating pain.^{46, 56}

The primary cause of osteoporosis is related to aging, and this is becoming more problematic as people continue to live longer. However, secondary causes of osteoporosis may also lead to fragility fractures of the spine and include steroids, alcoholism, low calcium intake, hormonal imbalances, and metabolic problems, including malabsorption of calcium through the gastrointestinal tract and renal disease.

Conventional medical management consists primarily of bed rest, narcotics, and braces. Pain from a vertebral compression fracture may take more than 1 year to resolve with this treatment. Surgical management may involve anterior and posterior approaches with instrumentation, for which outcomes are typically poor because the bone is inherently weak. This may lead to collapse and even neurologic deficits.

Vertebroplasty

Background

The technique of vertebroplasty was begun in the mid-1980s by a French neuroradiologist, Dr. Herve Deramond, who performed this procedure to treat a painful hemangioma of the cervical spine in a desperate patient.¹⁹ This procedure was based on the principle of treating benign tumors of bone in other parts of the body by injection of polymethylmethacrylate (bone cement). For this painful hemangioma, Deramond injected bone cement and completely ameliorated the patient's pain. He subsequently used the vertebroplasty technique to treat painful metastatic vertebral compression fractures with excellent results.

Vertebroplasty has been used to treat painful osteoporotic compression fractures with excellent results. The first vertebroplasties performed in the United States occurred in the mid-1990s.^{21, 25} In 1998, a modification of the vertebroplasty technique (*balloon kyphoplasty*) was designed to reestablish vertebral body height with the use of an inflatable balloon before fixation of the vertebra through the injection of bone cement.

In a review of the literature from France and the United States, more than 336 patients have received this treatment, and 90% of these patients experienced a dramatic reduction in or disappearance of pain, usually within 48 hours.^{10, 12, 21, 25, 35, 40} Average follow-ups were 1 to 3 years, but some have been for as long as 10 years. These patients continue to be free of their original fracture pain.

Complications rates have ranged from 1% to 6% and have included radiculopathies, rib fractures, bleeding, pulmonary embolus, and canal compromise.

Indications

In the United States, most vertebroplasties and balloon kyphoplasties are performed for osteoporotic vertebral compression fractures. However, vertebroplasty can also be performed for destructive osteolytic metastases, particularly when the patient is not a candidate for chemotherapy and radiation therapy (Box 26–1). Most vertebral hemangiomas

Box 26–1. Indications for Vertebroplasty

- Osteoporotic painful vertebral compression fractures
- Compression fractures of the vertebra due to metastatic disease
- Multiple myeloma
- Painful vertebral hemangioma

Figure 26–25. T1-weighted MR image demonstrating edema of a painful compression fracture of T7.

are asymptomatic, but for the few that cause considerable pain, vertebroplasty may be an effective treatment.

Technique

The selection of patients for vertebroplasty or balloon kyphoplasty should be based on correlation of findings on careful physical history and physical examination, plain films, MRI, and/or bone scanning (Fig. 26–25). We perform our physical examinations with fluoroscopy in an effort to correlate the focus of pain found on percussion directly over the spinous processes (Fig. 26–26). Vertebroplasty involves the placement of a large-bore (11- or 13-gauge) needle, with the tip positioned in the anterior third of the vertebral body. Percutaneous entry is used under multidirectional fluoroscopy or combined portable fluoroscopy and CT guidance.³⁸ A transpedicular approach is usually taken (Fig. 26–27), but a single posterior-lateral approach can be taken on the lower lumbar vertebrae.

For the smaller upper thoracic vertebrae, a costovertebral approach can be used if the pedicles are too small. Conscious sedation and a local anesthetic agent are appropriate for most patients.

Injection of the vertebra with iodine contrast medium (see Fig. 26–27C) can provide a vertebral venogram and a means of predicting unwanted runoff of the bone cement into the epidural veins or into the inferior vena cava. If exuberant filling of either epidural veins or the inferior vena cava is seen during contrast injection, unwanted embolization of bone cement to the lungs or the epidural veins can be avoided by injecting bone cement after it reaches a very doughy, viscous state.

Figure 26-26. Physical examination reveals point of tenderness by percussion, which was demarcated by a lead shot marker (arrowheads). This confirms that the patient's tenderness is emanating from the T7 compression fracture and correlates well with the MRI findings of marrow edema (see Fig. 26-25).

Because of the risk of infection, most operators administer prophylactic antibiotics either in the form of a broad-spectrum antibiotic such as cefazolin (Ancef) administered (2 g) intravenously or by mixing tobramycin powder (1.2 g) into the bone cement.^{10, 25}

To avoid unwanted embolization of the bone cement to either the epidural veins or the inferior vena cava and lungs, optimal visualization of the bone cement during the time of injection is extremely important. Therefore, maximum opacification of the bone cement is desired and is usually obtained by mixing in 6 g of sterile USP barium.

For vertebroplasty, filling of at least the anterior two thirds of the vertebra is desired. This is done under high pressure via 1-mL Luer-Lok syringes or a high-pressure injection device (Parallax Technology). The patient should not be moved until the remaining sample of bone cement in the mixing bowl has adequately hardened (usually 20 to 30 minutes).

Generally, most patients can be treated on an outpatient basis if they are carefully observed in a recovery area for 4 to 6 hours after the procedure.

Technique Notes

The patient should be left in the prone position until the sample methacrylate in the mixing bowl is completely hardened (20 to 30 minutes). The patient is then taken to the recovery area for 4 to 6 hours, after which discharge occurs. Follow-up patient visits are made within 24 hours, at 1 week, at 4 weeks, and then at 4-month intervals or as necessary (Box 26-2).

Box 26-2. Vertebroplasty Procedure

- *Informed consent*
- *Sterile set-up*
- *Needle placement*

For placement of large-bore needles under multidirectional fluoroscopic or combined CT portable fluoroscopic technique, the choice of entry depends upon size and configuration of the vertebra. Transpedicular approaches are most common. In the lumbar region, the orientation of the pedicle in relation to the vertebra is relatively horizontal; in the thoracic region, there is a posterior-anterior downward orientation of the pedicles relative to the vertebra. This means that in the thoracic area the operator should begin somewhat higher than normally anticipated. If the pedicles are too small in the upper thoracic region, a costovertebral approach can be used.

- *Vertebral venography*

Nonionic, intrathecally compatible iodine contrast medium is used. (If the patient is allergic to iodine contrast medium, gadolinium can be used.) Usually, the injection of 3 to 4 mL of contrast medium is adequate. If the contrast medium does not wash out of the vertebra before bone cement injection, injection of a small amount of saline into the vertebra usually eliminates any residual opacity.

- If there is overly exuberant flow of contrast medium into the inferior vena cava or into the epidural veins, the bone cement should be allowed to reach a highly viscous, doughy state before it is injected.
- *Mixing the bone cement*

There are various brands. Some provide more of a doughy consistency (Zimmer). Refrigeration of the bone cement overnight increases the working time. For opacification, 6 g of USP sterile barium per level is excellent.

We usually mix the bone cement and barium for about 1 minute and load the methacrylate into 1-mL syringes. We do not inject the bone cement until it becomes somewhat doughy in consistency (~3 to 4 minutes). The 1-mL syringes provide a high-pressure injection.

- *Injection of bone cement into the vertebra*

Injection is administered under direct fluoroscopic visualization, with the needles placed in the anterior third of the vertebra. The needle is initially filled, and the methacrylate is then injected slowly and progressively in a retrograde manner to fill the more posterior portions of the vertebra. Usually, injection of approximately 2 to 3 mL of bone cement on a side is adequate. If the methacrylate clogs in the needle, the stylet of the needle can be reinserted to push the methacrylate out from the needle tip and to clear the needle for further injection of bone cement.

Figure 26–27. Vertebroplasty.

A, At the T7 vertebra, 11-gauge needles have been directed through the T7 pedicles (*arrow*). In the thoracic region, the pedicles run posterior-anterior in a slightly superior-inferior direction, and thus the needle passage should be made to accommodate this configuration.

B, Lateral view demonstrating needle placement via a transpedicular approach. The needles have been extended to the anterior margins of the vertebra.

C, Vertebral venography showing runoff to the inferior vena cava. Caution should be exercised during injection of bone cement (polymethylmethacrylate). If the cement is too “runny,” it may embolize to the lungs.

D and *E*, Final distribution of bone cement throughout the T7 vertebra. The patient’s back pain disappeared within 1 hour of the procedure.

Figure 26-28. Balloon kyphoplasty, T12 vertebra. *A*, A 3-mm drill is directed through the anterior extent of the vertebral body after initial placement of 11-gauge needles and subsequent placement of a working cannula. *B*, Insertion of the inflatable balloon tamp before inflation. *C*, Inflation of the inflatable balloon tamp, anteroposterior view. *D*, Application of bone cement after height restoration. Note the rectangular, rather than previously wedge-shaped, configuration of the vertebral body.

Balloon Kyphoplasty

Although vertebroplasty is effective in ameliorating the pain of a vertebral compression fracture, it usually leaves a deformity of the vertebra (*kyphosis*). Prospective and retrospective studies have demonstrated decreased longevity of people with kyphotic vertebral compression fractures versus those without the fractures.²⁹ In addition, people with kyphosis who have underlying chronic obstructive lung disease continue to have exacerbating problems with their breathing as a result of decreased lung capacity.⁴⁷

Patients with severe kyphotic curvatures often complain of gastrointestinal problems of bloating and the feeling of partial bowel obstruction along with diminished appetite because the ribs and sternum press on the lower abdomen. Patients who have a severe kyphosis have a center of gravity that has shifted anteriorly, and they may move about in an unbalanced manner.^{9, 58} This may result in an increased risk of falls because of their incorrect balance position.

Balloon kyphoplasty is an attempt to reduce the unwanted effects of a kyphosis before the stability of the fracture is restored and the pain is removed. It is performed in a manner similar to that of vertebroplasty, but it also incorporates the addition of an inflatable bone tamp, which can help to reestablish vertebral body height before fixation with bone cement (Fig. 26–28). An added advantage of the use of the inflatable bone tamp may be that it creates a cavity within the fractured vertebra for which the injection of bone cement can be performed under low pressure, reducing the chances of unwanted leakage of methacrylate into adjacent venous or other structures (Box 26–3).

Box 26–3. Balloon Kyphoplasty Procedure

- *Informed consent*
- *Sterile set-up*
- *Percutaneous access to the vertebra similar to vertebroplasty with large-bore needles*
- *Insertion of guide pin through the large-bore needle*

Remove the large-bore needle. Insert the stiffening obturator over the guide pin. Place the working cannula over the guide pin and obturator with the tip of the cannula along the posterior margin of the vertebral body.

Remove the guide pin and obturator. Place a 3-mL drill through the working cannula, and through hand rotation advance the drill to the anterior third of the vertebra (see Fig. 26–28A). This creates a cavity for insertion of the inflatable bone tamp.

Remove the drill. Insert the bone tamp, and inflate under direct visualization with specified pressures. Maximum expansion of the bone tamp occurs when pressure dropoffs cease, the edge of the bone tamp reaches one of the end plates, or the bone tamp reaches its maximum volume.

- *Deflation and removal of bone tamp*

Mix the cement, as for vertebroplasty, with opacifying agents. Place bone cement in filler tube, and inject the same amount of bone cement to match the volume of the maximum balloon inflation of the bone tamp.

Results

Analysis of the first 24 kyphoplasties performed at the University of California, San Diego, revealed average vertebral body height restorations of 52% at the anterior vertebral body, 66% at the midvertebral body, and 53% at the posterior vertebral body. All patients in this group experienced dramatic pain relief, usually within hours of the procedure. There were no complications in this group.

At the time of the writing of this chapter, there are about a dozen centers at which kyphoplasties are performed. According to the Kyphon Corporation, 462 fractures have been treated in 291 procedures in 261 patients throughout these centers. Pain relief has been obtained in 90% of the cases, as confirmed by return to active daily living questionnaires. There have been no failures. The longest follow-up is 18 months. The procedure is well tolerated, and patients who require subsequent procedures look forward to undergoing the kyphoplasty.

The complication rate has been less than 2% (similar to that of vertebroplasty). No complication has been balloon-related.

Clinical trials for kyphoplasty are starting, with one randomized study comparing kyphoplasty with medical therapy. Other studies to evaluate height restoration, improved respiratory function, and improved quality of life are expected to follow.

Summary

Vertebroplasty is a procedure that can help stabilize a painful vertebral compression fracture and eradicate the pain. The balloon kyphoplasty is a modification of the vertebroplasty that provides an opportunity to restore vertebral body height before stabilization and pain ablation.

The vertebroplasty, kyphoplasty, and a variety of other image-guided spine interventions provide the radiologist with an opportunity to do much more than simply image. Using the knowledge of imaging anatomy, a radiologist can effectively intervene as both a diagnosing and a treating physician. To do so, however, requires that the radiologist also be willing to examine the patient, counsel the patient, and monitor the patient over time.

Part V

Imaging of the Chest

Edited by
John R. Haaga

Non-neoplastic Parenchymal Lung Disease

Janet E. Kuhlman

Evaluation of non-neoplastic parenchymal lung disease begins with careful examination of the posteroanterior (PA) and lateral chest films, together an invaluable source of information about the nature and extent of pulmonary diseases. Increasingly, however, conventional computed tomography (CT) and more advanced imaging techniques, such as high-resolution CT (HRCT, or thin-section CT), spiral and multidetector CT, ultrafast electron beam CT, and magnetic resonance imaging (MRI), have become integral parts of the evaluation process, serving as important adjuncts to the plain film for the purposes of detection, diagnosis, and characterization of parenchymal lung disease.

CT as an imaging modality has distinct advantages over conventional radiography in displaying the anatomy and pathology of the lung. The cross-sectional format of CT permits visual examination of the lung that is unencumbered by superimposed structures, such as the chest wall, heart, and pulmonary vessels. With the advent of HRCT, delineation of the lung parenchyma down to the level of the secondary pulmonary lobule, the basic building block of the lung, is possible. This additional information provided by HRCT allows a more detailed analysis of pathologic processes affecting the lung. Increasingly, HRCT is being used as the technique of choice to evaluate diffuse and focal lung diseases.^{142, 146, 168, 229, 230}

Spiral (or helical) CT takes advantage of new slip-ring technology and has revolutionized the way we look at the lung.^{40, 84, 112, 171, 200, 223} A continuously rotating detector combined with continuous table feed allows rapid data acquisition through the chest during a single breath-hold.⁸⁴ Spiral CT results in a gapless, volumetric acquisition that eliminates problems of slice misregistration caused by variations in the depth of inspiration.^{40, 84, 112, 171, 200, 223} The resulting data set is more accurate, more reproducible from one study to the next, and more quickly acquired. In the lung, spiral CT facilitates the process of evaluating small pulmonary nodules and allows the generation of three-dimensional (3D) images of the lung that are not degraded by respiratory motion (Fig. 27-1).^{40, 84, 112, 171, 200, 223} The faster acquisition times ensure evaluation of the lung during maximum vascular enhancement and may decrease the total volume of intravenous (IV) contrast material required for adequate enhancement.

Multidetector CT takes the advantages of spiral CT several steps further by combining rows of detectors and by interleaving or interspacing multiple helical data sets

that are simultaneously acquired. Multidetector scanners can cover greater distances, at faster speeds, with thinner slice thicknesses.

Ultrafast electron beam CT replaces the rotating detector gantry of conventional CT scanners with a deflectable electron beam and generates CT images in 0.1 to 0.05 second. Electron beam CT adds another dimension of speed to the data acquisition process and is fast enough to stop cardiac motion on displayed images, allowing detailed depiction of coronary artery calcifications. It has also been used to capture dynamic processes, such as air trapping resulting from small airway disease or changes in the caliber of the trachea and bronchi during various phases of the respiratory cycle.²¹³

Although MRI has a clear advantage over other imaging modalities in evaluating cardiac and vascular disorders of the chest, its role in the evaluation of parenchymal lung disease has been limited. Obstacles to lung imaging include respiratory motion and magnetic susceptibility effects caused by air-tissue interfaces. Rapid evolution of MRI technology suggests that some of these problems may be overcome in the near future. Promising areas under current investigation include MRI evaluation of the pulmonary circulation, arteriovenous malformations (AVMs), and other vessel-related disorders of the lung. Assessment of chest wall disease and peridiaphragmatic processes, which do not suffer as much from respiratory or magnetic susceptibility artifacts, already benefits from the multiplanar capabilities of MRI and its improved soft tissue contrast.

Techniques

Several approaches to examining parenchymal lung disease with CT exist, and no one method is optimal for all indications.¹⁴² Many authors advocate the use of standard conventional CT as the initial screening test, followed by a few select HRCT slices through areas of interest. In cases of occult pulmonary disease or a lung process that may affect the lung diffusely, surveying the entire chest at 1-cm intervals using HRCT techniques may be preferable. This multilevel HRCT examination is more likely to detect early or subtle manifestations of lung disease and is more accurate in determining the full extent of lung damage.

Multidetector and spiral CT are ideal for detecting and evaluating small pulmonary nodules and pulmonary emboli and for 3D imaging of the lung.^{40, 112, 200} Spiral CT can

Figure 27-1. Spiral CT facilitates the detection and evaluation of small pulmonary nodules (arrows). A, Axial view. Because the data are acquired in a continuous fashion during a single breath-hold, problems caused by slice misregistration are eliminated. Spiral CT data sets are ideal for generating multiplanar reconstructions, as in B, a sagittal reconstruction, and three-dimensional (3D) images of the lung, as in C. Nodule and surrounding emphysema are present in the posterior segment of the right upper lobe. C, A 3D image of the lung was created by applying volumetric rendering techniques to the spiral CT data set. The lung parenchyma, bronchovascular structures, major airways, and small nodule are displayed three-dimensionally without significant respiratory artifacts or image distortion. (From Kuhlman JE, Ney DR, Fishman EK: Two-dimensional and three-dimensional imaging of the in vivo lung: Combining spiral computed tomography with multiplanar and volumetric rendering techniques. *J Digit Imaging* 7:42-47, 1994.)

also be combined with high-resolution algorithms and thin-section techniques. Ultrafast CT, or cine-CT, is a prerequisite for evaluating airway physiology in real time, for example, capturing differences in lung attenuation and airway caliber that result from reversible or irreversible airway disease.²¹³

High-Resolution CT (Thin-Section CT)

HRCT combines the use of thinly collimated CT slices that are 1 to 1.5 to 2 mm in thickness, with a high-spatial-frequency algorithm that enhances edge detection.¹⁴² On many older CT models, the high-resolution algorithm is a bone reconstruction algorithm. On many newer CT models, a special high-resolution lung algorithm is available. Thin collimation decreases partial volume averaging and improves the ability of CT to demonstrate small pulmonary lesions. High-spatial-frequency algorithms, by decreasing the amount of smoothing of the image data, enhance edge detection and make lung structures look sharper. HRCT technical features increase spatial resolution but also increase the amount of noise visible in the image.

Although not essential, increases in kilovolt peak (kVp) and milliamperage (mA) settings may be used to improve signal-to-noise ratio in HRCT images.¹⁴² Field of view should be reduced to cover the lung parenchyma only, thus maximizing the fine detail of the lungs (Fig. 27-2). IV

contrast is not used for high-resolution CT examinations that are limited to evaluating the lung parenchyma.

To optimize an HRCT examination, additional considerations are important.^{141, 142, 227, 228} Retrospective targeting of the reconstructed image to a particular area of interest can further enhance depiction of abnormal lung parenchyma (see Fig. 27-2). Confusion caused by crowded pulmonary vessels and dependent lung edema or microatelectasis is minimized if HRCT scans are obtained at suspended end-inspiratory volume. If necessary, prone views can be taken to differentiate focal dependent edema or microatelectasis, commonly seen in the lung bases of normal patients, from early pulmonary fibrosis.

Although the best HRCT results are obtained with breath-holding techniques, this is not always possible in an acutely ill patient with respiratory compromise or in a pediatric patient.¹²⁶ Faster scan times, on the order of 1 second or less, are now available on many state-of-the-art scanners and greatly reduce respiratory motion artifacts, allowing for good-quality, high-resolution examinations to be performed even in these patients.

Image processing is also important. HRCT images are viewed at lung window settings. Exact settings vary depending on the scanner make and model, but typical window settings are in the range of 1650 (window width) and -600 (window center). Images of the mediastinum can be reconstructed using a standard soft tissue algorithm and viewed using mediastinal window settings of 410 (window

Figure 27-2. Advantages of high-resolution CT. A and B, Comparison of conventional CT and high-resolution CT techniques in a patient with a right middle lobe nodule. Conventional CT (A) with 8-mm slice thickness, 250 mA, 120 kVp. High-resolution CT (B) with 2-mm slice thickness, 260 mA, 137 kVp, and edge-enhancing algorithm. Note the increased detail and sharpness of the major fissures, the bronchi, and the tiny cysts within the lungs. The zone of dependent microatelectasis, a normal finding in many patients, is also more prominently visualized on the high-resolution CT scan. C, Targeted reconstruction, employing a smaller field of view, can be used with high-resolution CT techniques to optimize the display of fine lung detail, such as thickened interlobular septa (arrows) and “ground-glass” infiltrates.

width) and 3 (window center). Additional window settings are adjusted manually at the time of imaging to enhance depiction of subtle “ground-glass” opacities that are best appreciated on wider window settings.

Although HRCT algorithms are excellent for delineating diseases of the lung parenchyma, they are less appropriate for examining abnormalities of the mediastinum or the abdomen. The reconstruction algorithm used in HRCT makes detection of mediastinal adenopathy and focal liver lesions more difficult. High-resolution algorithms also tend to accentuate pleural thickness, an important factor to keep in mind during evaluation of patients with asbestos exposure for pleural disease. For assessment of a small pulmonary nodule for the presence of calcification, a standard lung algorithm should be used because the edge-enhancement properties of many HRCT algorithms make small nodules appear denser than they really are and can falsely simulate calcification.

Spiral or Helical CT

Spiral CT techniques can be easily adapted for evaluation of the lung.^{40, 84, 112, 171, 200, 223} Most helical scanners are capable of generating a series of consecutive scans lasting

1 second or less, obtained in a continuous fashion during a single breath-hold maneuver. The operator chooses the thickness of the slice collimation with a range of 1 to 10 mm. Table speed is set to between 1 and 10 mm/second. Pitch (table speed divided by slice thickness) is usually best kept between 1 and 2. The reconstruction algorithm and interval between reconstructed images (the degree of slice overlap) are chosen to suit the clinical problems at hand.

Numerous protocol variations exist. Two examples for lung evaluation are as follows:

1. A survey examination of the chest might use a slice acquisition thickness of 7 mm, a pitch of 1.4, a reconstruction interval of 5 mm, and a lung algorithm for lung images and a standard algorithm for soft tissue images.
2. A focused study with greater detail that will cover a shorter distance might use a slice acquisition thickness of 3 mm, a pitch of 1 to 1.7, and a reconstruction interval of 1 mm employing a high-resolution lung algorithm.

Total acquisition times and recommended mA and kVp vary by manufacturer. Once axial images are reconstructed, the spiral CT data set can be transferred to a free-standing workstation where multiplanar reconstructions and 3D image analysis can be performed (see Fig. 27-1).¹¹²

Whether or not IV contrast is required for the chest spiral CT examination depends on the clinical question to be answered and the type of disease process anticipated.

Multidetector CT

The possible protocol variations multiply rapidly with the additional capabilities of multidetector scanners. One example of a protocol in use for evaluating pulmonary emboli uses the following multidetector CT parameters:

- Slice thickness, 1.25 mm
- Reconstruction interval, 0.6 mm
- Table speed, 7.5 mm/rotation
- Time per rotation, 0.8 second

IV contrast (150 mL) is injected at 4 mL/second, with a scan delay time of 25 seconds. Scanning begins at the diaphragm and proceeds to the top of the chest. All images are reviewed on an independent workstation using a paging mode, and selected images are also viewed from hard-copy film.

CT Patterns and Signs of Non-neoplastic Lung Disease

As experience with CT accumulates, patterns and signs of non-neoplastic lung disease have emerged. Many of the HRCT patterns and signs are refinements of those first recognized on conventional CT of the lung. In an attempt to arrive at a differential diagnosis for focal or diffuse lung disease, it is helpful first to characterize the parenchymal CT abnormalities into one of three categories⁹⁸:

- Air space disease
- Interstitial disease
- Cystic lung disease

Once the predominant category has been established, the lung disease can be further characterized on the basis of patterns of distribution and by recognizing a few specific CT signs.

Categories of Lung Disease

Air Space Disease

One of the earliest manifestations of focal air space disease on CT scans is the presence of small 4- to 10-mm opacities called *acinar nodules*.¹⁴⁶ These are not true nodules when examined pathologically but, rather, represent clusters of alveoli that are filled with fluid, inflammatory cells, or blood, depending on the disease process. As air space disease becomes more severe and extensive, acinar densities coalesce to form larger opacities and eventually progress to lobular, subsegmental, segmental, lobar, and multilobar involvement (Fig. 27-3). Air-bronchograms on CT scans are hallmarks of air space consolidation, just as they are on conventional chest radiographs (Fig. 27-4).

Interstitial Disease

Features of interstitial disease on conventional CT and HRCT include nodules, reticulation, and thickening of the pulmonary septa (Fig. 27-5).^{20, 177, 197, 240} Interfaces that exist between the lung and the pleural surfaces, or between the lung and the bronchovascular bundles, become irregular and shaggy (see Fig. 27-5).²⁴⁰ HRCT supplements and enhances conventional CT in the detection of early interstitial lung disease by providing greater detail of the smaller, more peripheral lung elements and interlobular septa.

Cystic Lung Disease and Abnormal Air Spaces

Cystic disease of the lung encompasses a wide variety of pathologic processes that are characterized by "holes" or abnormal air-containing spaces within the lung parenchyma.¹¹⁴ Cystic structures identified on CT scans include blebs, bullae, cavities, pneumatoceles, "honeycombing," (see "Subpleural Distributions" later), dilated bronchi, and dilated terminal airways and alveolar sacs. Lung diseases that produce abnormal air spaces in the lung include cavitating pulmonary infections, vascular-embolic disorders, bronchiectasis, emphysema, pulmonary fibrosis, adult respiratory distress syndrome (ARDS), and unusual disorders such as Langerhans' histiocytosis, lymphangiomyomatosis, and tracheolaryngeal papillomatosis. The mechanisms by which abnormal air spaces are produced include focal ischemic necrosis of the lung, as seen with septic emboli; disruption of elastic-fiber networks, as found in emphysema; and retractile fibrosis with remodeling of the lung architecture, as seen in the honeycomb lung (Fig. 27-6).

Characterization of Lung Disease

Once lung disease has been characterized as air space, interstitial, or cystic in nature, it can be further analyzed as to its pattern and distribution. *Focal* lung disease may demonstrate specific CT signs that aid in narrowing the differential diagnosis. *Diffuse* lung disease may be evenly or unevenly distributed throughout the lung. It may affect primarily the central regions, the subpleural zones, or the tissues surrounding the bronchovascular structures. Different lung diseases tend to exhibit different patterns of distribution, and recognizing the patterns increases diagnostic accuracy and confidence.

CT Signs of Focal Lung Disease

Non-neoplastic Pulmonary Nodules

Etiology

CT evaluation of a known or suspected solitary pulmonary nodule makes up a significant part of any chest CT schedule. According to CT criteria,^{80, 90, 204, 205, 216, 217, 217a, 241} at least three benign causes of a solitary pulmonary nodule can be reliably identified:

- Calcified granulomas
- Hamartomas
- Pulmonary AVMs

Figure 27-3. CT features of focal air space disease. *A*, A small pulmonary infarct fills the air spaces of one or two secondary pulmonary lobules with hemorrhage, producing a small air space opacity on CT (arrows). *B* and *C*, As the air space disease resulting from the infarction becomes more extensive, smaller lobular opacities coalesce to form larger subsegmental and segmental areas of involvement (arrowheads). (*A* and *C*, From Kuhlman JE: CT of diffuse lung disease. Appl Radiol 20:17-21, 1991.)

Figure 27-4. Multilobar pneumonia. Air-bronchograms are a hallmark of air space disease on CT scans, as they are on plain films. (From Kuhlman JE: CT of diffuse lung disease. Appl Radiol 20:17-21, 1991.)

Granulomas. A well-circumscribed pulmonary nodule measuring 2 cm or less in diameter that demonstrates CT attenuation in the range of calcium on a phantom-calibrated, unenhanced CT scan of the chest is usually a *benign calcified granuloma* (Fig. 27-7).^{80, 90, 204, 205, 216, 217, 241} The absolute threshold value in Hounsfield units (HU) for designating calcification varies from one CT scanner and manufacturer to another, but it can be calibrated for any individual scanner using a phantom. When a solitary pulmonary nodule is not obviously calcified on CT scans but appears to be of higher CT density than soft tissue, the nodule's CT attenuation can be compared with a CT reference phantom for more accurate assessment.^{80, 90, 216, 217, 240} Nodules demonstrating CT attenuations greater than the CT reference phantom were benign in 90% of cases reported in one series.²¹⁶

In addition to the density of the nodule, the pattern of calcification is also important and must be either homogeneous throughout the nodule, in a pattern of concentric rings, or in a "popcorn" distribution to fit the CT criteria for benign calcification. The one exception is in the setting of metastatic osteogenic sarcoma. Lung metastases from osteogenic sarcoma are typically calcified in a homogeneous pattern. Although lung cancers and other malignan-

Figure 27-5. CT features of interstitial disease. A, Small interstitial nodules in a patient with sarcoidosis. Reticulation (B) and thickening of the pulmonary septa (C) in two patients with idiopathic pulmonary fibrosis. D, Irregular and shaggy interfaces between the lung and the fissures, pleural surfaces, and mediastinum are CT features characteristic of interstitial disease. Idiopathic pulmonary fibrosis. (A, B, and D, From Kuhlman JE: CT of diffuse lung disease. *Appl Radiol* 20:17-21, 1991.)

Figure 27-6. Mechanisms by which cystic or abnormal air spaces are created in the lung. (From Kuhlman JE: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

Figure 27-7. Benign calcified granuloma. Nodule is as dense as the ribs on soft tissue window settings and measures greater than 160 Hounsfield units on a calibrated, noncontrast CT scan.

Figure 27-8. A–C, Pulmonary hamartomas. CT can be used to identify fat within these two nodules (*arrows*).

cies may contain small areas of calcification, they rarely demonstrate calcification in one of the benign patterns described previously.

Finally, the morphology and edge of the nodule must also be considered. The presence of spiculation or irregularity of the margins of a nodule should greatly raise a concern for malignancy, even in the presence of calcification, because many such lesions are cancerous.²⁴¹

Hamartomas. The pulmonary hamartoma, a benign growth of multiple tissue components, may also be identified on the basis of CT attenuation properties.²⁰⁵ Hamartomas are composed of a number of tissues, including soft tissue, muscle elements, and fat. About 30% of hamartomas contain enough fat to be detected by CT, and CT identification of fat within a solitary pulmonary nodule is diagnostic of hamartoma (Fig. 27–8). The CT attenuation of fat is in the range of -20 to -160 HU or less and can be reliably measured by a region-of-interest (ROI) cursor.

Hamartomas are typically well-circumscribed, smooth, round, or lobulated nodules; 20% contain calcification, often in a popcorn distribution. When fat is identified within an area of air space consolidation rather than in a nodule on CT scans, this should suggest the diagnosis of *lipoid pneumonia*. Lipoid pneumonia is usually caused by the chronic use of mineral oil nasal drops.

Pulmonary Arteriovenous Malformations. The third cause of a benign solitary pulmonary nodule that can be recognized on CT scans is a pulmonary AVM. An enlarged feeding artery leading to a pulmonary nodule and an enlarged draining vein are characteristic features of a pulmonary AVM (Fig. 27–9). Dynamic CT scanning, performed after a bolus injection of contrast material, can be used to confirm the vascular nature of the lesion by following the enhancement pattern and time-density curves of the lesion, which parallel those of the heart and pulmonary arteries.

Enhancement of Benign and Neoplastic Nodules

After administration of IV contrast material, nodules that are not calcified on CT scans may show some enhance-

ment but do not show the degree and rapidity of enhancement seen with AVMs. Malignant nodules tend to enhance more than benign, inactive granulomas, which show very little or no enhancement. Studies by Swenson and others suggest that noncalcified nodules that show contrast enhancement above a certain threshold during the first 3 to 5 minutes after IV contrast injection are more likely to be neoplastic.^{217, 217a, 217b, 239a, 242} However, nodules caused by active inflammatory disease, such as active granulomas resulting from fungal infection or tuberculosis (TB), may also show significant contrast enhancement.²⁴² Additionally, false-negative results have been reported, including a few lung cancers that did not show enhancement above the target threshold value.²⁴²

By preprogramming a series of short helical or dynamic scans sequentially through a nodule under investigation, one can monitor nodule enhancement during a bolus IV injection of contrast material. The characteristics of malignant nodules are discussed further elsewhere in this text.

Vessel-Related Disorders

A number of vessel-related disorders of the lung produce focal lung disease, including *pulmonary infarcts*, *septic emboli*, *hematogenous metastases*, and *pulmonary vasculitis*.^{11, 33, 65, 78, 106, 109, 152, 186, 207} All of these disorders may show similar CT features, such as multiple peripheral nodules or wedged-shaped opacities that abut the pleura, that cavitate, or that demonstrate a feeding vessel.

The *feeding vessel sign* consists of a nodule or focal opacity that demonstrates a pulmonary vessel leading to it. The presence of a feeding vessel indicates either that the lesion has a hematogenous origin or that the disease process occurs in close proximity to small pulmonary vessels. The feeding vessel sign can be used to characterize lung disease that results from a disseminated neoplastic or infectious process that seeds the lung via the bloodstream, such as hematogenous metastases, septic emboli, and multiple pulmonary infarcts (Figs. 27–10 and 27–11).^{33, 65, 78, 106, 142, 150, 186, 207} This sign is also visible when vasculitis affects

Figure 27–9. Pulmonary arteriovenous malformations. A, CT shows a nodule with a feeding artery and draining vein. B, The vascular nature of the lesion can be confirmed by dynamic CT scanning after a bolus injection of contrast material and by noting that the nodule enhances and fades as rapidly as the heart and pulmonary arteries.

Figure 27-10. Vessel-related disorders. A and B, Infarct caused by septic embolus. CT with multiplanar reconstruction shows a peripheral, cavitating lesion abutting the pleura. Reconstructed sagittal and oblique images demonstrate a feeding vessel (arrow). (From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.) C-F, Acute pulmonary infarcts due to thromboembolic disease. C and D, Lung windows show two peripheral, wedged-shaped opacities that abut the pleura (arrows), compatible with a diagnosis of pulmonary infarcts. Feeding vessels lead toward the infarcts (arrowhead). E and F, In the same patient, spiral CT with IV contrast enhancement demonstrates filling defects (arrows) within the right and left pulmonary arteries caused by multiple pulmonary emboli.

Figure 27-11. Hematogenous metastases. CT shows multiple pulmonary nodules, each with a discrete feeding vessel leading to it (arrowheads). (From Kuhlman JE: CT of diffuse lung disease. Appl Radiol 20:17-21, 1991.)

the pulmonary vessels, as in Wegener's granulomatosis and lymphomatoid granulomatosis.¹⁰⁹

Wegener's Granulomatosis

Wegener's granulomatosis is a necrotizing granulomatous vasculitis that affects pulmonary vessels, most commonly the small and medium-sized arteries and veins.^{24, 34, 52, 236} Nodules and cavities are typical chest film findings.^{2, 117, 130} On CT scans, these cavities and nodules are often peripheral and pleura-based and demonstrate a prominent adjacent vessel to the lesions (Figs. 27-12 and 27-13).¹⁰⁹

In tissue studies, Wegener's lesions show central necrosis surrounded by a granulomatous reaction.^{74, 135, 136, 143, 198, 225} Frequently, a thrombosed vessel demonstrating active vasculitis is identified in close proximity to the necrotic lesion, and the resulting ischemia is believed to contribute to cavity formation within the granulomatous nodule (see Fig. 27-12).^{74, 135, 136, 143, 198, 225}

Wegener's granulomatosis may also present as patchy or diffuse pulmonary hemorrhage on a CT scan. This occurs when pulmonary capillaries are primarily involved by the vasculitic process (Fig. 27-14).¹³⁶

Thromboembolism

The role of multidetector and spiral CT in the evaluation of suspected *pulmonary thromboembolic disease* is evolving rapidly but remains controversial.^{14a, 183a} Large, prospective, properly designed accuracy trials are needed to provide reliable estimates of the sensitivity and specificity of spiral and multidetector CT in diagnosis of pulmonary emboli.^{14a, 183a, 239b} Remy-Jardin and colleagues demonstrated that spiral CT achieved a high degree of accuracy in identifying central pulmonary emboli down to the second-order to fourth-order pulmonary arteries.^{184a, 184b} In other studies, reported sensitivities of spiral CT vary from 53% to 100%, and specificities vary from 81% to 100%.^{14a, 67a, 183a, 184a, 184b, 239b}

An important limitation of spiral CT is the lower sensitivity for detecting smaller peripheral emboli in subsegmental arteries, the importance of which remains uncertain.^{67a} Detecting clots in obliquely oriented segmental vessels in the right middle lobe and lingula may be particularly difficult as well.^{184a} False-positive results also occur when hilar and intersegmental lymph nodes, unopacified pulmonary veins, or mucous plugs are misinterpreted on spiral CT as emboli.^{15a, 68a, 184a, 184b} Remy-Jardin and coworkers have shown that multiplanar images may provide additional, complementary information in difficult cases.^{184b}

Findings of acute pulmonary emboli include filling defects that wholly or partially occlude the contrast-opacified pulmonary arteries, or a "tail" of clot within an opacified vessel.^{116a, 184a, 184b, 239b} Chronic thrombi often appear as crescentic or laminar filling defects adherent to the walls of the pulmonary artery.^{90a, 184a, 239b} Calcification may be identified in chronic clots in patients with long-standing pulmonary hypertension.^{90a} Associated parenchymal lung findings in thromboembolic disease include the CT findings of acute or chronic pulmonary infarcts, and wedged-shaped, focal air space opacities that abut the pleura.^{34a} Other nonspecific findings in acute pulmonary embolus include pleural effusions. In chronic thromboembolic disease, the lung parenchyma may demonstrate mosaic attenuation, with areas of decreased attenuation associated with "pruned" or attenuated vessels.^{90a}

Bronchiolitis Obliterans Organizing Pneumonia

The clinical diagnosis of bronchiolitis obliterans organizing pneumonia (BOOP) is often a difficult and elusive one.^{14, 18, 32, 37, 49-51, 68, 145} Patients present with a subacute onset of nonspecific symptoms, including cough, dyspnea, fever, and flu-like illness. BOOP may be associated with autoimmune disorders, such as Sjögren's syndrome and polymyalgia rheumatica, or with collagen vascular and rheumatologic diseases; frequently, however, it is idiopathic. Although a definitive diagnosis of BOOP is usually made only by open lung biopsy, in the appropriate clinical setting certain CT features should suggest BOOP as a diagnostic possibility.

BOOP may have many CT appearances, but most cases demonstrate one of four patterns on CT scans: (1) a focal nodular form, (2) a form resembling pneumonia, (3) a pattern characterized by subpleural opacities, or (4) a pattern of ground-glass infiltrates (Figs. 27-15 to 27-19).^{22, 32, 147, 158, 173, 228}

When BOOP is more focal in nature, it appears on CT scans as multiple nodular or masslike areas of focal consolidation that occur primarily in the periphery of the lung (see Figs. 27-15 and 27-16).^{22, 147, 158, 173, 228} The opacities frequently conform in size and configuration to one or more secondary pulmonary lobules.¹⁷³ Often a small pulmonary artery or a small bronchiole can be traced into the center of the nodular area of consolidation, and a small air-bronchogram can be seen surrounded by the focal area of air space consolidation.²² This is a common pattern of BOOP identified on CT scans, and the pathologic features of the disease help to explain the CT appearance.

In BOOP, fibrovascular plugs of granulation tissue form

Figure 27-12. Wegener's granulomatosis. *A*, Chest film shows multiple ill-defined opacities and probable cavities. *B*, On this CT scan, a cavitating mass abutting the fissure and several tiny nodules abutting the pleura are identified. *C* and *D*, Several of the smaller lesions demonstrate a feeding vessel (arrowheads). *E*, Lung biopsy specimen shows one necrotic nodule with a surrounding granulomatous reaction (arrowheads) and an adjacent thrombosed arterial vessel resulting from vasculitis (arrow). (*B*, *C*, and *E*, From Kuhlman JE, Hruban RH, Fishman EK: Wegener granulomatosis: CT features of parenchymal lung disease. *J Comput Assist Tomogr* 15: 948-952, 1991.)

Figure 27-13. CT findings of Wegener's granulomatosis. A, Multiple nodules with feeding vessels (arrows). (From Kuhlman JE, Hruban RH, Fishman EK: Wegener granulomatosis: CT features of parenchymal lung disease. *J Comput Assist Tomog* 15:948-952, 1991.) B, Two pleura-based lesions (large arrows) resembling infarcts, and several smaller peripheral nodules (small arrows). C, Patient with long-standing Wegener's granulomatosis under treatment. Scarring, spiculation, and pleural reaction can be seen around peripheral pulmonary nodules (arrows).

Figure 27-14. This patient presented with hemoptysis caused by Wegener's vasculitis affecting primarily the capillaries of the lung. A and B, On CT scans, patchy air space filling is seen as a result of pulmonary hemorrhage. C, A few weeks later, a CT scan shows nearly complete clearing of the air space disease.

Figure 27-15. CT features of bronchiolitis obliterans with organizing pneumonia (BOOP).

A, Chest film shows ill-defined peripheral opacities.

B and C, On CT scans, nodular areas of focal consolidation are identified in the periphery of the lung, abutting the pleura. The opacities conform in size and configuration to one or more secondary pulmonary lobules. Small pulmonary vessels can be traced into the lesions.

D, Open lung biopsy demonstrates the classic histopathology of BOOP. The distal small airways are obliterated with fibrovascular plugs (arrows), and the inflammatory process has extended out from the obliterated bronchioles in a centrifugal fashion, filling the surrounding air spaces with organizing pneumonia (arrowheads).

(B–D, From Bouchardy LM, Kuhlman JE, Ball WC, et al: CT findings in bronchiolitis obliterans organizing pneumonia (BOOP) with x-ray, clinical, and histologic correlations. *J Comput Assist Tomogr* 17:352–357, 1993.)

in distal bronchioles and alveolar ducts.^{35, 88, 91, 239} The inflammatory or fibrotic process then extends out from the obliterated small airway in a centripetal or radial fashion into the surrounding alveolar spaces, producing organizing pneumonia (see Fig. 27-15). Nishimura and Itoh¹⁷³ have stressed the panlobular nature of BOOP and that its distribution on CT scans and pathologic examination frequently conforms to the margins of the secondary pulmonary lobule. Review of the anatomy of the secondary pulmonary lobule is illustrative.

The secondary pulmonary lobule is a polyhedral struc-

ture that can be thought of as the basic building block of the lung. Interlobular septa containing connective tissue, pulmonary veins, and lymphatics define the margins of the secondary pulmonary lobule, whose sides measure approximately 1 to 2.5 cm in length.^{73, 230} The secondary pulmonary lobule is made up of 3 to 12 acini and is supplied by several terminal bronchioles. A lobular core supplies the central portion of the secondary lobule and consists of a pulmonary artery and its accompanying bronchiolar branches. This lobular core or centrilobular complex can often be seen on HRCT as a small dot or centrilobular

Figure 27-16. CT features of bronchiolitis obliterans organizing pneumonia (BOOP), nodular form. CT shows multiple nodular opacities with air-bronchogram (*arrow*) and associated vessel (*arrowheads*). (From Bouchardy LM, Kuhlman JE, Ball WC, et al: CT findings in bronchiolitis obliterans organizing pneumonia (BOOP) with x-ray, clinical, and histologic correlations. *J Comput Assist Tomogr* 17:352-357, 1993.)

density within the center of the secondary pulmonary lobule.^{73, 230} Primarily, the pulmonary artery of the lobular core is seen on HRCT because visualization of the accompanying bronchiole depends on its wall thickness, not its diameter, which is below the resolution of HRCT. Normal intralobular bronchioles and interlobular septa usually are not detected on HRCT.²³⁰ Their presence usually indicates abnormal thickening of the bronchiolar walls or septal interstitium.

Because BOOP begins as an inflammatory process that obliterates small distal bronchiolar airways and secondarily spreads into the surrounding air spaces to fill secondary

Figure 27-18. CT features of bronchiolitis obliterans organizing pneumonia (BOOP), subpleural form. Irregular peripheral bands of increased CT attenuation parallel the pleural surfaces (*arrows*). An intervening zone of relatively spared lung can be seen between the pleural surface and the band. (From Bouchardy LM, Kuhlman JE, Ball WC, et al: CT findings in bronchiolitis obliterans organizing pneumonia (BOOP) with x-ray, clinical, and histologic correlations. *J Comput Assist Tomogr* 17:352-357, 1993.)

pulmonary lobules, it is easy to understand why areas of consolidation secondary to BOOP appear to be centered on small pulmonary arteries and small bronchi on CT examination.

As the organizing pneumonia of BOOP becomes more extensive, larger areas of consolidation are seen on the CT scan, and the CT appearance becomes indistinguishable from that of a bacterial pneumonia (see Fig. 27-17).

BOOP may also show other patterns on CT scans. Irregular bandlike areas of variable attenuation in the periphery of the lung are typical of some cases of BOOP (see Fig. 27-18), and subpleural reticulations can be seen in up to 23% of patients.^{14, 22} Patchy ground-glass infiltrates have also been reported in this disease (see Fig. 27-19).^{22, 173}

Figure 27-17. CT features of bronchiolitis obliterans organizing pneumonia (BOOP), pneumonic form. A large area of consolidation caused by BOOP is demonstrated on CT and is indistinguishable by appearance from a bacterial pneumonia. Air-bronchograms can be visualized. (From Bouchardy LM, Kuhlman JE, Ball WC, et al: CT findings in bronchiolitis obliterans organizing pneumonia (BOOP) with x-ray, clinical, and histologic correlations. *J Comput Assist Tomogr* 17:352-357, 1993.)

Figure 27-19. CT features of bronchiolitis obliterans organizing pneumonia (BOOP). Another CT presentation of BOOP is as diffuse, but patchy, "ground-glass" infiltrates. (From Bouchardy LM, Kuhlman JE, Ball WC, et al: CT findings in bronchiolitis obliterans organizing pneumonia (BOOP) with x-ray, clinical, and histologic correlations. *J Comput Assist Tomogr* 17:352-357, 1993.)

Figure 27-20. CT halo sign of invasive pulmonary aspergillosis. Three patients had acute myelogenous leukemia, prolonged aplasia owing to chemotherapy, and new-onset fever. In each case, an early focus of invasive pulmonary aspergillosis was identified with CT.

A and B, CT scans show a nodule (arrowhead) surrounded by a CT halo of intermediate attenuation (arrows) due to hemorrhagic infarction caused by the angioinvasive fungus. (From Kuhlman JE, Fishman EK, Siegelman SS: Invasive pulmonary aspergillosis in acute leukemia: Characteristic findings on CT, the CT halo sign, and the role of CT in early diagnosis. *Radiology* 157:611-614, 1985.)

C, The invaded thrombosed vessel is seen (arrow). (From Kuhlman JE: *Opportunistic fungal infection: The neutropenic patient with leukemia, lymphoma, or bone marrow transplantation*. In Kuhlman JE [ed]: *CT of the Immunocompromised Host*. New York, Churchill Livingstone, 1991.)

Figure 27-21. Gross pathologic specimen of invasive pulmonary aspergillosis shows an early focus of infection with surrounding hemorrhage (arrowheads) and invaded thrombosed vessel adjacent to nodule (arrow). (From Kuhlman JE, Fishman EK, Burch PA, et al: CT of invasive pulmonary aspergillosis. *AJR Am J Roentgenol* 150:1015-1020, 1988.)

Figure 27-22. CT pattern of progression and resolution of invasive pulmonary aspergillosis. *A*, Early infection in leukemic patient with pancytopenia from chemotherapy. CT halo. *B*, After the white blood cell count has returned to normal, the lesion undergoes cavitation and air-crescent formation. *C*, With further healing, a residual thin-walled cyst and linear scar to the pleura remain. (A-C, From Kuhlman JE, Fishman EK, Burch PA, et al: CT of invasive pulmonary aspergillosis. *AJR Am J Roentgenol* 150:1015-1020, 1988.)

Invasive Pulmonary Aspergillosis

The CT *halo sign* can be used to identify invasive pulmonary aspergillosis in the patient with acute leukemia who is undergoing aplasia-producing chemotherapy.^{27, 61, 97, 100, 103, 104, 107} This sign consists of a round pulmonary mass or nodule with a surrounding halo of intermediate CT attenuation (Fig. 27–20). The halo represents hemorrhage around a focal area of lung infarction caused by the *Aspergillus* organism that invades pulmonary vessels (Fig. 27–21).^{76, 176} Other angioinvasive infections (mucormycosis, *Candida*, *Torulopsis*, and angioinvasive *Pseudomonas*) may produce similar CT findings, but *Aspergillus* is by far the most common organism to produce this CT finding in the specific clinical setting of a leukemic patient with prolonged bone marrow aplasia following chemotherapy.

In patients with acute leukemia undergoing chemotherapy, lung infection by invasive pulmonary aspergillosis follows a typical pattern of progression and resolution (Fig. 27–22).^{27, 61, 97, 100, 103, 104, 107} As the bone marrow recovers from aplasia and the white blood cell count returns to normal, the pulmonary lesions begin to cavitate, producing the familiar air crescent sign. With further healing, the lesions tend to shrink and fade from the periphery, leaving behind thin-walled cysts or linear scars to the pleura.

In the nonleukemic, non-neutropenic patient, the CT halo sign is less specific. It may represent something other than invasive pulmonary aspergillosis, such as other types of angioinvasive infections, hemorrhagic metastases, or any process that produces a nodule with surrounding hemorrhage or edema.

Rounded Atelectasis

Rounded atelectasis is another cause of benign focal lung disease that can be differentiated from malignancy using CT criteria (Fig. 27–23).^{48, 127, 128, 144} CT features of rounded atelectasis include a pleura-based mass found adjacent to an area of pleural thickening and associated with volume loss of the involved lobe. Sweeping or curling into the mass are adjacent vessels and small bronchi forming a *comet's tail* or *vacuum cleaner sign* that course down to the mass from the pulmonary hilum.^{48, 127, 128, 144}

On pathologic examination, rounded atelectasis represents a focal area of atelectatic lung that rolls or curls up on itself, taking the nearby bronchi and blood vessels along with the infolding lung in the process. Rounded atelectasis is always found adjacent to an area of pleural thickening, and the process is thought to begin with an adhesive pleural effusion or pleural reaction, which entraps the adjacent atelectatic lung. Although many cases of rounded atelectasis are the result of asbestos-related pleural disease, other causes of pleural reaction may produce similar findings.

Bronchiectasis

Dilatation of one or more bronchi results in bronchiectasis.¹⁷⁹ Most causes of bronchiectasis are irreversible and include such diverse categories of disease as immunologic defects (X-linked agammaglobulinemia), ciliary dyskinesia syndromes (Kartagener's syndrome), genetic disorders (cystic fibrosis), childhood or repeated infections (pertussis, TB), and congenital abnormalities of the bronchial

Figure 27–23. CT features of rounded atelectasis. A and B, Chest film shows ill-defined mass in the posterior left lower lobe (arrowheads). The patient underwent coronary bypass surgery, and now evidence of pleural thickening with blunting of the left costophrenic angle can be seen.

Figure 27-23. Continued. C-H, Typical features of round atelectasis are visualized by CT. A rounded pleura-based mass is present, with adjacent pleural thickening (arrowheads). Vessels and lung markings curl into the lesion, producing the comet's tail or vacuum cleaner sign (arrows). The predisposing cause in this patient was not asbestos exposure but previous thoracic surgery.

Figure 27-24. CT signs of bronchiectasis. The signet ring sign (*arrowheads*) consists of the dilated bronchus (the ring) and its accompanying pulmonary artery (the signet). A large mucous plug fills one of the dilated bronchi (*arrows*). (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air spaces in the lung. *Radiographics* 13:47-75, 1993.)

wall (Williams-Campbell syndrome).²¹⁴ In each case, the protective airway mechanisms that maintain airway sterility and airway clearance are disrupted. This leads to repeated bacterial infections, colonization, and mucous plugging, followed by a destructive inflammatory response and resultant bronchiectasis.

CT has replaced bronchography as the noninvasive method for diagnosis and evaluation of bronchiectasis.^{45, 82, 166, 169, 202, 210, 226} Dilated bronchi demonstrate a number of characteristic features on CT scans, and when bronchiectasis affects primarily the larger proximal airways, it is not difficult to recognize. Because each bronchus is accompanied by a pulmonary artery, bronchiectasis commonly produces a *signet ring sign* (Fig. 27-24). The dilated bronchus seen in cross-section forms the ring; the accompanying pulmonary artery forms the signet of the ring.

In cylindrical bronchiectasis, when the dilated bronchus is sectioned longitudinally by the CT scanning plane, the parallel thickened airway walls resemble a *railroad track* or *tram track*. If the bronchiectasis is varicose in nature,

the structure seen on the CT scan resembles a *string of pearls* with areas of dilatation alternating with areas of constriction (Fig. 27-25). In cystic bronchiectasis, when dilated bronchi are grouped together and cut in cross-section, an appearance resembling a *cluster of grapes* is seen (Fig. 27-26).

Air-fluid levels resulting from retained secretions or superimposed infection are commonly identified in dependent portions of cystically dilated bronchi. When dilated bronchi are filled with inspissated material, mucoid impaction results. On a CT scan, *mucous plugs* are identified by recognizing the branching tubular nature of the opacity on multiple CT sections (Fig. 27-27 and see Fig. 27-24).

Bronchiectatic cysts are larger air spaces that develop in severe forms of bronchiectasis, such as cystic fibrosis. Such cysts are recognized by their connection to a dilated proximal bronchus. In contrast to blebs or bullae, bronchiectatic cysts demonstrate discrete, often thickened walls and may be multiloculated (Fig. 27-28).^{70, 221}

In *central bronchiectasis*, there is marked dilatation of

Figure 27-25. CT signs of bronchiectasis in a patient with advanced cystic fibrosis. When a dilated bronchus is sectioned longitudinally by the CT scanning plane, it often demonstrates a *string of pearls* configuration with alternating areas of dilatation and constriction (*arrows*). (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air spaces in the lung. *Radiographics* 13:47-75, 1993.)

Figure 27-26. CT signs of bronchiectasis. Cystically dilated bronchi when grouped closely together may demonstrate a cluster-of-grapes appearance on CT (*arrowheads*). The relative oligemia (*large arrow*) of some of the pulmonary segments can be compared with more normal lung (*curved arrow*) in this patient with advanced bronchiectasis. This is an example of mosaic attenuation. The subtle differences in CT attenuation of the lung parenchyma reflect both the degree of vascular perfusion and the air space inflation of each segment. Relative underperfusion, resulting from reflex shunting of blood away from hypoxic segments, and hyperinflation of affected segments caused by air trapping contribute to decreased lung density on CT. (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air spaces in the lung. *Radiographics* 13:47-75, 1993.)

the proximal bronchi with relative sparing of more distal segments. Central bronchiectasis is a hallmark of *allergic bronchopulmonary aspergillosis* (Fig. 27-29).⁴²

Allergic bronchopulmonary aspergillosis is characterized on plain films and CT by central bronchiectasis and abundant mucous plugging. This disease typically produces fleeting opacities, which come and go on plain films, and some of the more dramatic examples of the finger-in-glove sign of mucous plugging. A history of refractory asthma is

the clue to the diagnosis, which can be confirmed by a set of clinical and laboratory criteria that include elevated IgE levels, precipitating antibodies against *Aspergillus*, peripheral blood eosinophilia, immediate and late skin reactions to *Aspergillus* antigen, and *Aspergillus* mycelia in sputum or mucous plugs.^{225a}

Recognizing *bronchiolectases*, or disease affecting the smaller peripheral airways, is more difficult (Fig. 27-30). This is particularly true in cases of *panbronchiolitis* caused

Figure 27-27. A-C, A new focal lung opacity was seen on chest films after fever developed in a patient with cancer who was receiving chemotherapy. With a spiral CT data set, multiplanar reconstructions of the lung identify the opacity as a branching, tubular structure compatible with a diagnosis of mucous plug. Distinct small pulmonary arteries (*arrows*) accompany the dilated, mucus-filled bronchi.

Figure 27-28. Bronchiectatic cysts are recognized on CT by identifying their connection to a dilated bronchus (*arrows*). Histologically, the walls of bronchiectatic cysts are lined with collagenous fibrous tissue.

Figure 27-29. Central bronchiectasis is a characteristic feature of allergic bronchopulmonary aspergillosis. A and B, Posteroanterior and lateral chest films show central thin-walled cystic lesions (*arrows*). C and D, CT more clearly identifies the abnormalities as dilated, tubular bronchi (*arrowheads*) and areas of cystic bronchiectasis. An air-fluid level can be visualized (*arrows*). (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air spaces in the lung. *Radiographics* 13:47-75, 1993.)

Figure 27–30. A–C, Panbronchiolitis. Bronchiolectases or bronchiectatic disease of the smaller peripheral airways may have an appearance on CT that mimics multiple tiny nodules. CT shows peribronchial thickening and mild dilatation of the proximal bronchi. In addition, multiple tiny dots in a centrilobular location are noted; they result from bronchiolectases of the smaller, peripheral airways. The CT appearance has been described as “tree-in-bud” opacities (*arrows*).

by viral or bacterial infections or other inflammations. Thickened peripheral bronchioles, because of their small size and short length, do not demonstrate the same longitudinal features seen in larger airways and may be mistaken for small nodules. If dilated, these distal small airways may mimic small cavitating nodules. The appearance of inflamed distal bronchioles often resembles small buds on a tree branch and has been described with the phrase *tree-in-bud opacities*.^{80a}

CT Features of Diffuse Lung Disease

Diffuse lung disease demonstrates many patterns of distribution on CT scans. These patterns are often helpful in characterizing the nature of the lung disease and arriving at a limited differential diagnosis for the pulmonary process.¹⁵⁵

Diffuse air space disease may be distributed primarily centrally or peripherally, or it may affect both the central and the peripheral zones of the lung. A few diffuse diseases of the lung produce an abnormality of the lung parenchyma referred to as ground-glass opacities (Fig. 27-31).^{146, 157} These opacities may be distributed homogeneously or in a patchy or mosaic pattern, or they may be limited to the centrilobular region of the secondary pulmonary lobule.^{4a}

Diffuse interstitial disease and diffuse cystic lung disease may also have several patterns of distribution, including peribronchial and subpleural locations. Examples of cystic lung disease that produce diffuse patterns of distribution include panlobular emphysema and lymphangiomatosis.

Ground-Glass Opacities

The ground-glass opacity is characterized by a subtle increase in CT attenuation of the lung parenchyma that does not obliterate the outlines of the bronchi or pulmonary vessels (see Fig. 27-31).^{4a, 155, 157} It may be homogeneous and diffuse or more uneven in its distribution, producing a patchwork pattern often described by the term *mosaic attenuation*. Diseases that typically produce ground-glass opacities on CT scans include *Pneumocystis carinii* pneumonia (PCP), cytomegalovirus (CMV) pneumonia, alveolar proteinosis, acute pulmonary edema, extrinsic allergic alveolitis, and the acute alveolitis stage of desquamative interstitial pneumonitis (DIP) and usual interstitial pneumonitis (UIP) (see Fig. 27-31).^{64, 110, 206} HRCT enhances detection of subtle ground-glass opacities, particularly in cases in which the chest film or the conventional CT scan are normal or show equivocal findings (Fig. 27-32).

Patchwork or Mosaic Attenuation Patterns

Sometimes the parenchymal abnormality is less uniform and distinctly patchy in its distribution, with areas of normal lung interspersed with abnormal zones. This pattern may be thought of as a "patchwork" pattern because of the striking, sometimes bizarre and mosaic appearance of the lung on CT scans (see Figs. 27-31 and 27-32). Patchy differences in lung CT attenuation are seen in a number of diffuse pulmonary processes, such as *obliterative bronchiolitis* (*bronchiolitis obliterans*), *bronchopulmonary dysplasia*, *asthma*, *hypersensitivity pneumonitis*, *PCP*, *DIP*, *pul-*

monary hemorrhage, and *chronic thromboembolic disease*.^{98, 110, 126, 213a}

Diseases that produce mosaic attenuation on CT scans fall into three basic categories:

- Airway disease
- Vascular disease
- Infiltrative disease

The causes of the underlying differences in CT attenuation vary, depending on the disease category.^{213a, 238b}

In some lung diseases, abnormal areas of lung are those that demonstrate increased CT attenuation either because the alveolar spaces are filled with edema fluid or cells (see Figs. 27-14 and 27-32) or because the relative amount of air in the alveolar space is decreased as a result of encroaching, thickened interstitium. In other diseases, such as advanced cystic fibrosis (see Fig. 27-26), obliterative bronchiolitis, and bronchopulmonary dysplasia (Fig. 27-33), the abnormal areas of lung are those that demonstrate decreased CT attenuation relative to the surrounding normal lung, as a result of focal air-trapping and reflex oligemia caused by vasoconstriction. In chronic thromboembolic disease, the lung pattern has been described by some authors as "mosaic perfusion" to reflect the belief that differences in pulmonary vascular perfusion contribute in large part to the differences in lung attenuation visualized on CT scans.^{114, 126, 138}

Obliterative Bronchiolitis (Bronchiolitis Obliterans)

Also known as *constrictive bronchiolitis*, obliterative bronchiolitis has many causes: past infection, Swyer-James syndrome, inhalational injury, and drug use. It is also seen in association with collagen vascular diseases (rheumatoid arthritis, lupus, and scleroderma); in bone marrow transplant recipients with chronic graft-versus-host disease; and as the primary manifestation of chronic rejection in lung and heart-and-lung transplant recipients.^{119a}

Swyer-James Syndrome

Swyer-James syndrome is a form of obliterative bronchiolitis that results from a childhood viral infection that goes on to produce postinfectious bronchiolitis obliterans (see Fig. 27-33B-D).^{137a, 152a} Typical findings include a small, hyperlucent lung that demonstrates air-trapping on expiratory films or CT. A small pulmonary artery on the affected side is characteristic. On CT scans, one can better appreciate not only the small main pulmonary artery but also diminution and pruning of all the pulmonary artery branches on the affected side.

Bronchiectasis is a CT feature of Swyer-James syndrome that is not widely recognized but is often present.^{137a, 152a} CT studies have shown that lung changes in Swyer-James syndrome are not exclusively unilateral.^{152a}

Centrilobular and Peribronchiolar Patterns

A few lung diseases produce CT abnormalities that are confined, at least initially, to the region immediately surrounding the central core bronchioles of the secondary pulmonary lobule. On first examination, these CT abnormalities may be mistaken for tiny nodules, but closer in-

Figure 27-31. "Ground-glass" infiltrates on CT are subtle areas of increased CT attenuation of the lung parenchyma that do not obscure the margins of the bronchi or pulmonary vessels. A and B, Ground-glass infiltrates caused by *Pneumocystis carinii* pneumonia. C, Edema resulting from acute cocaine overdose causes ground-glass infiltrates and bilateral pleural effusions. D and E, Alveolar proteinosis produces typical CT features, including patchy ground-glass infiltrates and prominent interlobular septa (arrows) that are regularly thickened as a result of septal edema.

spection reveals that each represents a nodular opacity centered around the centrilobular complex of the secondary pulmonary lobule and its small bronchiolar branches.

Diseases that cause this type of CT abnormality are often characterized histologically by peribronchiolar infiltration with inflammatory cells or lymphocytes or with

granulomatous reaction. Early graft-versus-host disease affecting the lung in the bone marrow transplant recipient produces such a CT appearance because of infiltration of lymphocytes around the small bronchioles. Panbronchiolitis, whether caused by infection or exposure to an irritant, may produce a similar CT appearance.^{4, 4a}

Figure 27-32. The patient is an immunocompromised heart transplant recipient with fever. *A*, The chest film was interpreted as unchanged from a baseline chest film following surgery. *B* and *C*, CT scan shows dramatic “ground-glass” infiltrates in a patchy distribution, a pattern suggestive of *Pneumocystis carinii* pneumonia, which was subsequently confirmed at bronchoscopy. (*A–C*, From Kuhlman JE, Kavaru M, Fishman EK, Siegelman SS: *Pneumocystis carinii* pneumonia: Spectrum of parenchymal CT findings. Radiology 175:711–714, 1990; and Kuhlman JE: CT of the immunocompromised and acutely ill patient. In Zerhouni EA [ed]: CT and MRI of the Thorax. New York, Churchill Livingstone, 1990.)

Figure 27-33. Mosaic attenuation, three cases.

A, Case 1. CT scan of bronchopulmonary dysplasia and bronchiolitis obliterans in a child demonstrates a pattern of mosaic attenuation. Segments of the lung (*arrows*) show decreased CT attenuation. Within these segments, the pulmonary vessels are small and attenuated as well. A combination of reflex vasoconstriction and hyperinflation due to air trapping probably accounts for the lower CT attenuation in these areas. (From Kuhlman JE: CT of diffuse lung disease. *Appl Radiol* 20:17-21, 1991.)

B-D, Case 2. Swyer-James syndrome. CT shows a small, hyperlucent right hemithorax with bronchiectasis and mosaic attenuation on the right side. Perfusion is decreased, and the caliber of the pulmonary artery branches is markedly decreased on the right. D, The main pulmonary artery on the right is also small, compared to the artery on the left.

E, Case 3. Mosaic attenuation accentuated on expiratory high-resolution CT views indicates air trapping. The patient is a 32-year-old woman with a history of asthma who uses an inhaler.

Bronchogenic spread of TB may also produce a focal form of this pattern when expectorated caseous material from a TB cavity is spread through the airways, becomes inspissated in small bronchioles, and secondarily causes bronchiolar dilatation, thickening, and peribronchiolar infection and inflammation (Fig. 27-34).¹⁶¹ This produces the tree-in-bud appearance on CT scans. TB and other mycobacterial infections often produce some of the most dramatic examples of tree-in-bud opacities,^{80a} but this finding is not necessarily specific for mycobacterial infections and can be seen in other causes of bronchiolitis, both infectious and inflammatory.

Diffuse Panbronchiolitis

Diffuse panbronchiolitis, the disease entity, is a chronic inflammatory disease of unknown cause found most commonly in Asians but occasionally in Americans and Europeans.^{4, 4a} Clinically, patients present with chronic cough, dyspnea, wheezing, and sputum production. Associated chronic paranasal sinusitis is common.

CT findings include bronchiolectasis and milder bronchiectasis, peribronchiolar thickening, tree-in-bud opacities, and peripheral areas of mosaic attenuation. Bronchiolar changes are the dominant finding on CT scans and these changes are strikingly diffuse, involving all lobes.^{4, 4a} Tissue studies show infiltration of the walls and tissues, centering on the respiratory bronchioles, with lymphocytes, plasma cells, and histiocytes. This inflammatory process causes secondary dilatation of the more proximal airways, beginning with the terminal bronchioles.^{4, 4a}

Progression to respiratory failure is often rapid and the prognosis is poor. Treatment with long-term, low-dose erythromycin has produced some success; disease regression or progression can be monitored with CT.^{4, 4a}

Figure 27-34. Peribronchiolar densities of “ground-glass” opacity and consolidation, resulting from spread of tuberculosis, look like tiny, “fuzzy” nodules on CT scans (called “tree-in-bud” opacities). The apparent nodules actually represent inspissated caseous material in small bronchioles, with surrounding peribronchiolar inflammation and infection.

Bronchovascular Distributions

A number of lung diseases are distributed primarily along the bronchovascular bundles and within their surrounding lymphatic interstitial tissues. Lung diseases with a distinct bronchovascular distribution include *sarcoidosis* and *Kaposi's sarcoma* (KS).^{105, 108, 165, 208, 235}

Sarcoid

In addition to septal thickening, reticulation, and fibrosis, pulmonary sarcoid is characterized on CT scans by the presence of small nodules adjacent to the bronchovascular structures (see Fig. 27-5A).^{108, 208} These nodules represent aggregates of granulomas that have a predilection for the peribronchovascular lymphatics.

Kaposi's Sarcoma

Kaposi's sarcoma, when it involves the lung, is another example of peribronchovascular disease.¹⁶⁵ The sarcoma infiltrates along and around the bronchovascular bundles and the surrounding lymphatics. On CT scans, pulmonary lesions resulting from Kaposi's sarcoma radiate from the pulmonary hila in a distinctive pattern, often appearing to encase and coat the bronchi (Fig. 27-35).^{105, 165, 235}

Beaded Septum Sign

Thickening of the interlobular septa and bronchovascular interstitium is a CT feature of many diffuse interstitial lung diseases and may be smooth, irregular, or nodular. Smooth thickening of the interlobular septa is seen in diseases such as *interstitial pulmonary edema* and *alveolar proteinosis*. Irregular septal thickening, often accompanied by distortion of lung architecture, is characteristic of diseases causing interstitial pulmonary fibrosis. Prominent nodular thickening of the interlobular septa, reminiscent of beads on a string, is an appearance seen in cases of lymphangitic carcinomatosis, some granulomatous diseases, and occasionally silicosis (Fig. 27-36).^{20, 146, 160, 240} Lymphangitic carcinomatosis produces the most dramatic cases of nodular septal thickening (see Fig. 27-36).

Pathologic correlation has shown that the beaded appearance is caused by endolymphatic deposits of metastatic tumor.^{146, 160, 185} Sarcoidosis is an example of a granulomatous disease that may produce a similar appearance on CT scans (see Fig. 27-36).

Subpleural Distributions

A few lung diseases produce CT abnormalities that are initially most severe in the periphery of the lung, the so-called “subpleural zone.” Such diseases include idiopathic pulmonary fibrosis (fibrosing alveolitis), asbestosis, BOOP, eosinophilic pneumonia, and certain types of drug-induced lung disease (Fig. 27-37). The subpleural CT abnormalities may consist of ground-glass opacities, arcades of reticulation, or a meshwork of small cystic spaces known as *honeycombing* (see Fig. 27-37).²⁴⁰

Honeycombing is a distinct form of pulmonary damage and lung remodeling that consists of multiple small cystic air spaces ranging in size from 1 to 10 mm. Histologically, the walls of the cystic spaces are composed of granulomatous or fibrous tissue, and the process has a distinct predi-

Figure 27-35. A-C, Bronchovascular distributions. In three patients with Kaposi's sarcoma (KS) involving the lung, the distinct tendency of KS to spread along the peribronchovascular interstitium is shown. On CT, pulmonary lesions caused by KS radiate out from the pulmonary hila and often appear to encase or coat the bronchi (arrows). (A, From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991. B, From Kuhlman JE, Fishman EK, Burch PA, et al: Diseases of the chest in AIDS: CT diagnosis. Radiographics 9:827-857, 1989. C, From Kuhlman JE: CT of diffuse lung disease. Appl Radiol 20:17-21, 1991.)

Figure 27-36. The beaded-septum sign. *A–C*, Prominent nodular thickening of the interlobular septa and the peribronchovascular interstitium due to sarcoidosis results in a CT appearance reminiscent of beads on a string. *D*, The most dramatic examples of the beaded septum sign are the result of lymphangitic spread of tumor, in this case lung cancer. (*D*, From Kuhlman JE: CT of diffuse lung disease. *Appl Radiol* 20:17–21, 1991.)

lection for the subpleural zones.¹⁸¹ Honeycombing is the common final pathway for many diffuse lung diseases that produce interstitial fibrosis, including fibrosing alveolitis, DIP, pneumoconiosis, sarcoidosis, rheumatoid lung, scleroderma, and others.^{120, 181, 211, 215, 232}

The presence of ground-glass opacities in the subpleural zone is often indicative of reversible lung injury. Treatment with corticosteroids or removal of the offending agent, such as a toxic drug, may reverse the pulmonary damage. The presence of honeycombing, however, is usually indicative of permanent, irreversible lung injury.²¹¹

Application of CT in Evaluation of Non-neoplastic Lung Disease

CT features are used to characterize diffuse and focal lung diseases for diagnosis, and HRCT improves both diagnostic accuracy and specificity.^{19, 20} In addition to its diagnostic role, however, CT has other important clinical applications, including early detection of lung disease,

quantification of lung damage, monitoring lung response to therapy, and detection of complications.

Early Detection and Diagnosis

Early detection of pulmonary disease is crucial in a number of clinical settings. Detection of occult lung infection in the immunocompromised patient may improve survival.²⁷ Early documentation of lung damage caused by pneumoconiosis has important environmental health and medicolegal implications. Early identification of pulmonary drug toxicity may lead to interventions that prevent irreversible lung injury.¹⁰¹

Opportunistic Lung Infection

An immunocompromised patient with unexplained fever or respiratory symptoms presents a common and difficult clinical problem. CT has been used successfully to detect and characterize opportunistic infections in patients with leukemia, acquired immunodeficiency syndrome (AIDS),

Figure 27-37. Subpleural distributions.

A, Early CT evidence of pulmonary damage resulting from bleomycin toxicity is seen in the subpleural zones (arrows). Increased reticular markings parallel the pleural surfaces and are most prominent posteriorly. (From Kuhlman JE: The role of chest computed tomography in the diagnosis of drug-related reactions. *J Thorac Imaging* 6:52-61, 1991.)

B, Idiopathic pulmonary fibrosis causing arcades and reticulation in the subpleural zone.

C, More advanced pulmonary fibrosis with honeycombing. Lung diseases that produce pulmonary fibrosis and honeycombing usually demonstrate the most severe damage in the periphery of the lung, in the subpleural zone, and at the lung bases. (From Kuhlman JE: CT of diffuse lung disease. *Appl Radiol* 20:17-21, 1991.)

and disorders treated with bone marrow transplantation (Fig. 27-38) (see Figs. 27-20, 27-22, 27-32).^{27, 97, 100, 103, 104, 107, 110} HRCT aids in the early detection of lung infection in these patients. CT patterns and signs help to characterize the nature of the infection and direct invasive biopsy procedures to areas of the lung most affected. CT is also helpful in monitoring response of lung infection to appropriate therapy and in detecting relapse of infection.

Acquired Immunodeficiency Syndrome

When routine chest films fail to reveal a cause of unexplained fever or respiratory symptoms in a patient with AIDS, CT plays an important diagnostic and management role (see Fig. 27-38). CT can detect early or subtle lung infection when chest films remain negative or equivocal. In the patient with AIDS who may have many reasons to have fever or symptoms, the ability of CT to confirm the presence or absence of significant lung infection is critical in expediting the diagnostic workup. CT patterns of parenchymal lung involvement may suggest the most likely diagnosis, and CT can be used to select the diagnostic approach most likely to yield a positive culture specimen.

P. carinii Pneumoniae Infection

PCP is still one of the most common life-threatening lung infections to occur in patients with AIDS in industrialized countries.^{1, 30, 31, 46, 93, 99, 105, 164} PCP can have a variety of presentations, from acute fulminant respiratory failure to a more insidious onset with nonspecific symptoms of nonproductive cough, malaise, and low-grade fever.⁹³ In a patient with AIDS, this more insidious presentation is more common.

The classic chest film findings of PCP are well known and include bilateral ground-glass infiltrates in a perihilar or sometimes upper lobe distribution.^{1, 31, 46} The diagnosis is straightforward in patients who demonstrate these findings. Early in the course of infection, however, the chest film may appear normal or show only minimal increased lung markings, and a reported 10% of patients with documented PCP have normal or equivocal chest films.⁴⁶ In this setting, CT can be used to confirm or exclude the presence of parenchymal lung infiltrates.

CT patterns of PCP are varied, but the most common pattern is of diffuse or patchy, ground-glass infiltrates that do not obscure bronchovascular margins (Fig. 27-39).¹¹⁰ Increased interstitial markings can also be seen, particularly

Figure 27-38. Unexplained fever in a patient with acquired immunodeficiency syndrome (AIDS). **A**, Chest film shows central venous line but no obvious infiltrates. **B**, CT identifies multiple inflammatory nodules with feeding vessels (arrows), compatible with a diagnosis of septic emboli. The source of the septic emboli was found to be the central venous catheter that had become infected. (B, From Kuhlman JE, Fishman EK, Burch PA, et al: Diseases of the chest in AIDS: CT diagnosis. *Radiographics* 9:827-857, 1989.)

Figure 27-39. *Pneumocystis carinii* pneumonia (PCP): CT patterns of involvement. **A**, Diffuse "ground-glass" infiltrates. (From Kuhlman JE, Kavuru M, Fishman EK, Siegelman SS: *Pneumocystis carinii* pneumonia: Spectrum of parenchymal CT findings. *Radiology* 175:711-714, 1990.)

E, From Kuhlman JE: CT of the immunocompromised and acutely ill patient. In Zerhouni EA [ed]: CT and MRI of the Thorax. New York, Churchill Livingstone, 1990; F, From Kuhlman JE, Fishman EK, Burch PA, et al: Diseases of the chest in AIDS: CT diagnosis. Radiographics 9:827-857, 1989; G, From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.)

H, Solitary pulmonary nodule, an unusual manifestation of PCP seen in a few patients with AIDS.

in patients who have had repeated *Pneumocystis* infections (20% to 40% of patients), because of the interstitial fibrosis that develops as the infection heals.

Another CT pattern of PCP, which is quite different in appearance, occurs with the cystic form (Fig. 27-40).^{*} On CT scans, the cystic form of PCP is characterized by one or more thin-walled cysts or cavities that are somewhat irregular in shape and may be coarse or delicate in appearance. Surrounding ground-glass infiltrates are often present. This form of PCP may also be associated with CT manifestations of disseminated infection, including enlarged lymph nodes with calcifications found in the mediastinum and abdomen, and other calcifications in the liver, spleen, and kidneys (Fig. 27-41).^{99, 183}

Many patients with cystic PCP or lymph node and visceral calcifications caused by *Pneumocystis* infection were reported to be receiving aerosolized pentamidine for prophylaxis against PCP. The aerosolized drug may par-

tially clear or partially suppress the pulmonary infection, but it may not attain high-enough concentrations in the blood to prevent dissemination of the *Pneumocystis* organism. The chronic infection that remains in the lung may predispose to cystic cavity formation. More recently, aerosolized pentamidine has been less often used as a prophylactic agent, having been replaced by other, more effective drugs. Despite this change, the cystic form of PCP continues to be seen and some report an increasing frequency of this pattern of presentation.^{20a}

A rare CT presentation of PCP is the *solitary pulmonary nodule*.^{13, 110} A nodule may form in those individuals positive for the human immunodeficiency virus (HIV) who have less severe immunosuppression and can still mount a granulomatous response to the infection (see Fig. 27-39D). Pleural effusions are an uncommon finding in uncomplicated PCP. Rare cases of pleural effusions caused by disseminated *Pneumocystis* infection have been reported, and pleural calcifications may be demonstrated.^{20a} More often in the patient with AIDS, the cause of a pleural effusion is a bacterial, fungal, or mycobacterial infection; lymphoma;

Figure 27-40. Cystic forms of *Pneumocystis carinii* pneumonia (PCP).

A, CT scan of a 31-year-old man with acquired immunodeficiency syndrome (AIDS) and documented PCP shows a multitude of thin, delicate-walled cysts.

B and C, CT scan of another patient with PCP shows irregular cystic lesions with coarse walls and surrounding infiltrates.

D and E, PCP has resulted in multiple thin-walled cysts (arrows), complicated by bilateral pneumothoraces (arrowheads).

E, At autopsy, cystic lung lesions in this patient corresponded to discrete foci of necrotic debris surrounded by a thin wall of fibrous tissue (arrows). The surrounding lung showed organizing intra-alveolar and interstitial pneumonitis with marked inflammatory changes of nearby vessels, compatible with a diagnosis of vasculitis.

(A and C, From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air spaces in the lung. *Radiographics* 13: 47-75, 1993.)

Figure 27-41. Disseminated *Pneumocystis carinii* pneumonia (PCP) infection.

A, CT shows characteristic enlarged lymph nodes with calcifications. (From Kuhlman JE: CT evaluation of the chest in AIDS. In Thrall J [ed]: Current Practice in Radiology. St. Louis, Mosby-Year Book, 1993.)

B and C, Calcifications caused by disseminated PCP can also be seen in the spleen (arrow in B), abdominal lymph nodes (arrows in C), liver, and kidneys (arrowheads in C) in patients with disseminated PCP infection. Low-attenuation splenic lesions in C are the result of PCP splenic abscesses. (B, From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.)

or Kaposi's sarcoma. Although less well recognized, PCP infection can also cause airway abnormalities, including bronchiolitis and bronchiolitis obliterans.^{20a}

Several ancillary CT findings may be identified in patients with PCP or HIV disease. Apical and paraseptal bullae and spontaneous pneumothoraces are often noted in these relatively young patients (Fig. 27-42 and see Fig. 27-40).^{15, 111, 139, 170, 195} In a patient with AIDS, pneumothoraces are often difficult to resolve because of persistent air leaks. They may require more invasive procedures than simple chest tube placement, including pleurodesis, lung stapling, or pleurectomy to reexpand the lung.

Fungal Infection

In patients with AIDS, fungal infections involving the lungs usually present as multiple nodules or cavities (Fig. 27-43).^{96, 99, 105, 164} When present, fungal lung infection usually suggests disseminated disease. Other nonpulmonary manifestations of fungal disease, such as CT findings of esophagitis with esophageal wall thickening or focal lesions in the liver, may be the first indication of a disseminated fungal infection both in patients with AIDS and in other immunocompromised hosts (Figs. 27-44 and 27-45).

Any number of fungal species may cause pulmonary infection in the AIDS patient, including *Candida albicans*, *Coccidioides immitis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*. Infections caused by *Aspergillus* oc-

cur in patients with AIDS but much less frequently than they occur in other immunocompromised patients such as those with leukemia and prolonged neutropenia. This is because the body's immune response to *Aspergillus* infection requires only intact neutrophils and macrophages rather than healthy T cells or antibodies.

Neutrophil function is relatively preserved in AIDS patients until end stages of the disease. *Aspergillus* infections are seen, however, in AIDS patients who are taking corticosteroids or multidrug regimens that suppress neutrophil counts. *Cryptococcus* is the most common fungal pathogen to affect the lungs in patients with AIDS, almost always (>90% of cases) in conjunction with infection of the central nervous system.

Nocardial Infection

Nocardia is yet another opportunistic organism that is increasingly being recognized in the patient with AIDS.^{96, 99, 105} On CT scans, *Nocardia* infection may start out as a small inflammatory nodule but eventually develops into a cavitary mass or more extensive cavitary pneumonia involving one or more segments or lobes of the lung (Fig. 27-46).

Although the unusual opportunistic infections are usually emphasized in regard to pulmonary infections in AIDS, it is important to keep in mind that bacterial infections, often severe, aggressive, and recurrent ones, occur fre-

Figure 27-42. A–C: Apical and paraseptal bullae (arrows) in a patient with acquired immunodeficiency syndrome (AIDS) and repeated *Pneumocystis* infections. (From Kuhlman JE, Kavura M, Fishman EK, Siegelman SS: *Pneumocystis carinii* pneumonia: Spectrum of parenchymal CT findings. Radiology 175:711–714, 1990.)

quently in patients with AIDS, including those caused by *Streptococcus pneumoniae*, *Staphylococcus pneumoniae*, and *Haemophilus influenzae*.

Tuberculosis

Of increasing concern is the resurgence of TB as a significant communicable pulmonary infection in the United States, resulting in part from the AIDS epidemic.²²⁴ Emergence of multiresistant strains poses an ever-growing threat to public health on a global scale.

CT manifestations of pulmonary TB depend to a large extent on the health of the individual's immune system (Figs. 27-47 to 27-55). In the immunocompetent host, cavitation is one of the hallmarks of reactivation TB.^{56, 167} Cavities develop when centers of granulomatous reaction to the TB bacillus undergo caseation necrosis. On CT scans, cavities owing to TB can be thick-walled or thin-walled and are indistinguishable from those caused by other atypical mycobacterial species.^{6, 36, 56, 134, 167, 238}

Often with the development of tuberculous cavitation, the necrotizing process erodes into the tracheobronchial tree and the expelled tuberculous material spreads by the endobronchial route to other parts of the lung.

Typical CT features of bronchogenic spread include patchy areas of air space disease consisting of poorly defined nodular opacities measuring from 3 to 10 mm in diameter.^{56, 59, 80a, 167} Compared with the smaller discrete

nodules found in miliary TB,^{8, 71} the nodular opacities seen in bronchogenic spread are nonuniform in size and unevenly distributed.

Various terms have been used to describe these nodular opacities, including acinar nodules, acinose lesions, acinar shadows, and tree-in-bud opacities.^{80a} Pathologically, the lesions seen on CT scans correspond to peribronchiolar foci of infection and granulomatous reaction that are centered around the terminal respiratory bronchioles and their surrounding alveoli.^{10, 56, 80a, 167, 182} In cases of suspected TB, CT can be used to identify a small or occult cavity that is the source of the bronchogenic spread and to demonstrate the full extent of the infection, which is often widely scattered in both lungs.

If the host's immune system and the ability to mount a granulomatous response are intact, the reactivated infection is often contained and healing begins with the deposition of collagen and scar tissue around areas of caseous necrosis.⁸ Eventually, dystrophic calcifications form within granulomatous nodules, lymph nodes, and fibrotic strands, and the lung assumes the characteristic appearance of chronic fibrocalcific TB. Further scarring leads to lung distortion, bronchiectasis, volume loss, and cicatrization atelectasis and compensatory emphysema. Fibrotic, masslike lesions may form in the lung apices and may be difficult to distinguish from apical lung cancers or scar carcinomas on the basis of CT appearances alone.²³⁸

Figure 27-43. Disseminated cryptococcal infection. Chest film (A) and CT (B, C) show multiple pulmonary nodules.

Figure 27-44. Cytomegaloviral esophagitis. Marked thickening of the esophageal wall is evident on the CT scan. Oral contrast material is retained within the dilated, inflamed esophagus. (From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.)

Figure 27-45. Disseminated candidiasis. CT shows multiple filling defects in the liver caused by fungal abscesses (arrows). (From Kuhlman JE: CT of the immunocompromised and acutely ill patient. In Zerhouni EA [ed]: CT and MRI of the Thorax. New York, Churchill Livingstone, 1990.)

Figure 27-46. Nocardiosis in a patient with acquired immunodeficiency syndrome (AIDS). A. Initial CT scan on a patient with positive status for human immunodeficiency virus (HIV) infection shows a small inflammatory nodule in the right lower lobe. B. *Nocardia* infection has progressed to a large necrotic cavity. C. *Nocardia* infection in another patient with AIDS presented as a multilobar cavitory pneumonia. (C, From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.)

Figure 27-47. A–C, Mycobacterial infections. Cavities may be thin-walled (A) or thick-walled (B). (B, From Kuhlman JE, Deutsch JH, Fishman EK, Siegelman SS: CT features of thoracic mycobacterial disease. *Radiographics* 10:413–431, 1990.) C, Miliary tuberculosis. CT reveals innumerable tiny nodules distributed homogeneously throughout the lungs.

Figure 27-48. CT features of bronchogenic spread of mycobacterial disease. A and B, CT scan shows a large cavity in the right upper lobe and a smaller cavity on the left. Widely scattered areas of bronchogenic spread (arrows) are identified, demonstrating a "tree-in-bud" pattern. The patient has a right-sided aortic arch.

Figure 27-49. A and B, On these CT scans, areas of bronchogenic spread of tuberculosis appear as poorly margined, “fluffy” nodular densities of variable size.

Figure 27-50. A and B, CT features of chronic fibrocalcific tuberculosis (TB) include scarring, calcified granulomata, bronchiectasis, architectural distortion, and fibrotic masses.

Figure 27-51. Ranke's complex. CT image shows the calcified parenchymal scar (Ghon's lesion) (arrow) and the calcified hilar nodes representing healed regional lymphatic involvement from the initial tuberculosis infection.

Figure 27-52. Simon's foci, an example of healed sites of tuberculosis (TB) seeded to the lung apices at the time of the primary TB infection. The masslike opacity seen in the right apex was the result of healed TB in this case, but on the basis of the CT appearance alone, it is indistinguishable from that of lung cancer. Such opacities require close, serial follow-up to ensure stability in size over time or biopsy, in some cases, to exclude neoplasm. (From Kuhlman JE, Deutsch JH, Fishman EK, Siegelman SS: CT features of thoracic mycobacterial disease. *Radiographics* 10:413-431, 1990.)

Figure 27-53. A and B, Aspergillomas, growing in old tuberculous cavities, are identified on CT.

Figure 27-54. A and B, Tuberculosis in a patient with acquired immunodeficiency syndrome (AIDS). CT shows multiple inflammatory lung masses and bulky mediastinal nodes (arrows) resulting from tuberculosis (TB). Lymphadenopathy is the rule rather than the exception in patients with AIDS and TB. (From Kuhlman JE: CT evaluation of the chest in AIDS. In Thrall J [ed]: *Current Practice in Radiology*. St. Louis, Mosby-Year Book, 1993.)

Figure 27-55. Tuberculosis in a patient with advanced acquired immunodeficiency syndrome (AIDS). A woman with status positive for human immunodeficiency virus (HIV) infection was shown at autopsy to have bilateral pulmonary infiltrates (A), extensive lymphadenopathy (B, arrows), and multiple lytic bone lesions (B and C, arrowheads) caused by widely disseminated tuberculosis. (From Kuhlman JE: AIDS-related diseases of the chest. In Kuhlman JE [ed]: CT of the Immunocompromised Host. New York, Churchill Livingstone, 1991.)

Frequently on CT scans, evidence of earlier TB infection can be found in the form of old healed cavities or sequelae, such as^{56, 102}:

1. *Ghon's lesion*, the parenchymal scar or granuloma that occurs at the site of initial TB infection. This lesion is often calcified.
2. *Ranke's complex*, consisting of a parenchymal scar and the associated calcified lymph nodes in the pulmonary hilum or mediastinum. The presence of this complex suggests regional lymphatic spread.
3. *Simon's foci*, or healed residua of TB seeded to the lung apices at the time of primary infection.

Chronic TB cavities may permanently scar the lung and remain open even after sterilization. These chronic cavities may become complicated by superimposed infection or colonization with *Aspergillus* fungi that form mycetomas.¹⁹⁰

Although TB produces many chronic lung changes, disease activity cannot be determined on the basis of CT appearances alone. Fibrotic areas of lung and cavities that look inactive on chest radiographs or CT may in fact harbor viable organisms.^{56, 238} The radiologic stability of TB-induced lung changes, however, can be assessed with

serial chest films or serial CT scans. Follow-up CT examinations have become an important adjunct to sputum cultures in assessing response to treatment in infected patients.

In part because of the declining exposure rate of children to TB, a larger number of first-time exposures are occurring in adulthood, making cases of primary rather than reactivation TB in the adult more common than before. Mediastinal and hilar adenopathy is often an indication of primary TB infection.^{81, 123}

Tuberculosis in Special Patient Populations

A number of individuals are at increased risk for development of active TB, including older, debilitated, and malnourished patients and patients with AIDS.^{56, 81, 154, 167, 194} Special considerations also apply to patients with sarcoidosis and silicosis, in whom the prevalence of TB is increased.^{56, 81, 154, 167, 194, 238}

Patients with AIDS are particularly susceptible to mycobacterial infections both from *Mycobacterium tuberculosis* and from other atypical organisms, such as *M. avium-intracellulare* (MAI), *M. avium complex* (MAC), and *M. kansasii*.^{56, 134} In 10% to 20% of patients with AIDS, *M.*

avium-intracellulare infections are detected sometime during their life from blood, sputum, or bone marrow cultures. At autopsy, more than 50% of these patients are found to be infected. Despite these statistics, pulmonary infiltrates caused by *M. avium-intracellulare* are considerably less common than those caused by TB.¹³⁴

The most common CT manifestation of *M. avium-intracellulare* infection is diffuse adenopathy. Regardless of mycobacterial species, however, the normal granulomatous response to mycobacterial infection is poor or absent in the patient with AIDS, and disseminated disease is more common than in the immunologically competent host.^{6, 56, 134}

The AIDS population is particularly vulnerable to the spread of TB. In some parts of Africa, the combination of AIDS and TB has become epidemic. Manifestations of TB in the patient with AIDS depend on the degree of immunosuppression. In a patient with early HIV infection and milder immunosuppression, TB presents in a more classic fashion with cavitary disease and bronchogenic spread. TB that occurs in the setting of more severe immunosuppression or full-blown AIDS is more often atypical and aggressive in its manifestations, presenting in a manner more reminiscent of primary TB, primary progressive TB, or miliary TB.^{96, 102}

In the patient with advanced AIDS, widely disseminated and extrapulmonary disease and multiple pulmonary masses with significant adenopathy are not uncommon presentations of TB. Mediastinal and hilar adenopathy as a manifestation of TB in an AIDS patient is the rule rather than the exception. After administration of contrast material, tuberculous lymph nodes demonstrate characteristic low-attenuation necrotic centers and rim enhancement on CT scans.^{13, 81, 123, 154} In addition, traditional tests for TB exposure (e.g., the tuberculin skin test) are unreliable in patients with AIDS because most patients are anergic.

M. avium-intracellulare in Older Women

M. avium-intracellulare infection can also strike otherwise healthy, immunocompetent hosts. A distinct subtype has been reported in women between ages 50 and 90 years who have no underlying illness but present with a chronic, persistent cough. This subtype has a fairly characteristic CT appearance, with scattered areas of mild tubular bronchiectasis associated with nodular opacities and tree-in-bud forms. Cavitation is less common than in TB.^{70a, 153a}

Pulmonary Drug Toxicity

Early detection of drug-induced lung toxicity is another application of HRCT that is under current investigation.* Patients with respiratory symptoms who are receiving bleomycin, methotrexate, amiodarone, or other potentially toxic agents to the lung benefit from CT evaluation (Figs. 27-56 to 27-61). Early detection of drug-induced pulmonary damage increases the likelihood that lung damage will be reversible when the drug is withdrawn.

*See References 16, 17, 26, 28, 115, 116, 163, 172, 187, 188, and 209.

Bleomycin

In cases of *bleomycin lung*, HRCT has been more sensitive than chest radiographs in detecting early pulmonary toxicity, more accurate in quantifying the extent of pulmonary damage, and more helpful in monitoring disease progression or resolution.^{16, 17} The extent of pulmonary damage, as seen on CT scans, correlates well with measurements of impaired gas transfer and pulmonary function.^{16, 17}

CT features of bleomycin lung toxicity include linear reticulations, fibrotic bands, and nodular opacities that may mimic pulmonary metastases or recurrent tumor (see Fig. 27-58).^{16, 163, 188} These changes often appear first in the periphery of the lung and at the lung bases, paralleling the pleural surfaces (see Fig. 27-37).^{16, 163, 188} As the pulmonary toxicity becomes more severe, the reticular and nodular opacities coalesce to form large confluent opacities. Diffuse air space disease can also be seen with acute bleomycin

Regardless of the offending agent, early CT findings of drug-induced pulmonary toxicity are often confined to the subpleural zone. The apparent susceptibility of this region to lung toxicity may be related to the limited collateral airflow within the region or to the increased pressure and friction the zone experiences from the overlying pleura.⁵⁴

Amiodarone

Amiodarone is an antiarrhythmic agent that can cause significant and potentially irreversible pulmonary toxicity.^{62, 132, 175, 237} The drug is used primarily to treat refractory life-threatening arrhythmias. Early recognition of pulmonary toxicity is important because prompt discontinuation of the drug often results in resolution of toxicity.^{62, 175}

Unfortunately, few radiographic or laboratory findings are specific for amiodarone toxicity. Symptoms are also nonspecific, making early diagnosis of pulmonary toxicity on the basis of clinical evidence difficult. Onset of symptoms may be insidious, and symptoms caused by amiodarone toxicity, such as pleuritic chest pain, shortness of breath, malaise, and low-grade fever, may be similarly produced by cardiac decompensation, pneumonia, or pulmonary infarction, all common concurrent problems in heart disease patients.^{62, 175} Fortunately, because of its unique chemical composition (which contains three iodine moieties), amiodarone—when deposited in sufficient quantities within the lung—can be recognized by its high CT attenuation, which aids in diagnosis (see Figs. 27-59 to 27-61).^{28, 115, 116, 172, 187, 209}

On unenhanced scans, CT features of amiodarone lung toxicity include areas of consolidation or focal atelectasis showing high CT attenuation in the range of 80 to 110 HU.^{28, 115, 116, 172, 187, 209} The high-attenuation areas frequently abut the pleura, show adjacent pleural reaction, and may be wedge-shaped. Increased attenuation is also frequently demonstrated in the liver, spleen, thyroid gland, and occasionally in the heart muscle. Nonspecific pulmonary infiltrates, interstitial infiltrates, mixed alveolar and interstitial disease, and conglomerate masses may also be seen.^{28, 115, 116, 172, 187, 209}

Nonenhanced CT findings of high-attenuation parenchymal abnormalities are thought to be related to the iodinated

Figure 27-56. CT detection of drug-induced lung toxicity. Patient with recurrent lung cancer receiving ipomeanol, an investigational chemotherapeutic agent known to cause potential lung toxicity. *A*, CT shows development of a band of increased attenuation in the subpleural region, not detected on plain films (arrow). *B*, After discontinuation of the drug, the abnormality resolved.

Figure 27-57. *A* and *B*, Methotrexate pulmonary toxicity. The patient, a 59-year-old woman who was taking methotrexate for treatment of severe psoriasis, experienced subacute onset of fatigue, shortness of breath, and a nonproductive cough. CT shows patchy "ground-glass" infiltrates that were difficult to appreciate on chest radiographs. Cultures were negative for infection, and a lung biopsy specimen showed changes consistent with a diagnosis of methotrexate lung toxicity.

Figure 27-58. Bleomycin lung toxicity, CT features. A and B, CT shows nodular opacities, which may be mistaken for tumor recurrence or metastases but are actually caused by bleomycin toxicity, proven by biopsy. C, CT can be used to follow the progression or resolution of pulmonary toxicity. In this case, the nodular opacities progressed to larger areas of confluence. D, After discontinuation of the drug, a follow-up CT scan shows nearly complete resolution of the pulmonary lesions.

chemistry of the drug and its prolonged half-life within the lung.* Amiodarone is known to accumulate in high concentrations within the lung and the liver, where its half-life is 15 to 60 days.^{137, 201} Trapped by foamy macrophages, the drug becomes incorporated within lysosomes, where the cationic, amphophilic drug interacts with phospholipids to form a drug-lipid complex that resists biodegradation.† Characteristic lamellar inclusion bodies form within the lysosomes and interfere with lipid degradation and surfactant turnover, ultimately inducing a fibrotic reaction within the lung. These unique properties of amiodarone and the use of CT to discriminate attenuation levels provide a means of identifying those patients with significant pulmonary accumulation of the drug.

Recognizing amiodarone-induced lung changes in non-enhanced CT scans is particularly important in those patients who present with pleuritic chest pain. At least three cases of acute pulmonary decompensation have been re-

ported that occurred after pulmonary arteriography was attempted in patients who presented with pleuritic chest pain caused by amiodarone lung toxicity. Performing pulmonary arteriography in these patients to exclude pulmonary infarction should be avoided if possible.²³⁷

High-Attenuation Parenchymal Abnormalities

A few other disease processes can produce high-attenuation parenchymal abnormalities on CT scans, as follows:

1. *Metastatic pulmonary calcifications* occurring as the result of hyperparathyroidism from renal failure or from the infusion of large amounts of calcium salts in children with congenital heart disease can cause high-attenuation consolidations on CT scans.^{113, 131}
2. Focal and multifocal, high-density lung opacities have been reported in cases of *amyloid*, probably resulting from dystrophic calcification within areas of amyloid accumulation.
3. *Pulmonary ossification* in patients with long-standing

*See References 9, 29, 39, 44, 67, 77, 85, 115, 116, 124, 137, 162, 187, 189, and 201.

†See references 9, 29, 39, 44, 62, 67, 77, 85, 124, 137, 162, and 189.

Figure 27-59. Amiodarone toxicity. A 69-year-old man with chronic obstructive pulmonary disease, ischemic cardiomyopathy, and ventricular arrhythmias required antiarrhythmic medication. He presented with a 2-week history of increasing shortness of breath and pleuritic chest pain.

A and B. Chest film shows ill-defined opacity or area of focal atelectasis (arrows) and left pleural effusion.
C and D. Nonenhanced CT scan shows the focal lung opacity demonstrating high attenuation on soft tissue window settings (arrow) compatible with a diagnosis of amiodarone toxicity. Bronchoscopy was negative for tumor and for infection and yielded abundant foamy macrophages.

E and F. Other CT evidence of amiodarone exposure includes dense thyroid and dense liver resulting from the iodine content of the drug, which accumulates in these organs.

Figure 27-60. Amiodarone toxicity. *A* and *B*. The patient, a 40-year-old woman with arrhythmias who had been taking amiodarone for 32 months, presented with pleuritic chest pain and shortness of breath. *A*, Noncontrast CT shows a large, wedge-shaped area of consolidation in the right lung base (arrows). A band of atelectasis is noted adjacent to the left heart border (arrowheads). *B*, Both areas demonstrate high attenuation on soft tissue window settings (arrows). The increased attenuation of the heart muscle is a result of amiodarone deposition (arrowheads). (From Kuhlman JE, Tergen C, Ren H, et al: Amiodarone pulmonary toxicity: CT findings in symptomatic patients. *Radiology* 177:121-125, 1990.)

mitral stenosis can produce high-density air space opacities in the lung parenchyma.^{238a}

Occupational Lung Disease

The use of CT, especially HRCT, in the evaluation of occupational lung diseases is rapidly expanding.^{3, 5, 86, 184} A number of reports suggest that HRCT is superior to conventional radiographs and standard CT in the detection of pulmonary damage resulting from asbestosis and pneumoconiosis. HRCT is being used to detect evidence of

occupational lung disease, to determine the extent of the damage, and to follow the disease progression.

CT features of different types of pneumoconiosis are beginning to be recognized and characterized. HRCT findings that have been described in *silicosis* include micronodules, subpleural nodules, conglomerate masses, and focal emphysema (Fig. 27-62).¹⁸⁴

CT has become an important adjunct to conventional radiographs in the evaluation of *asbestos-related diseases*.^{3, 5, 86} CT is more sensitive and specific than plain films for identifying and documenting the presence of *pleural*

Figure 27-61. High-density infiltrates on noncontrast CT, differential diagnosis. *A*, High-density atelectatic lung measuring 105 Hounsfield units because of amiodarone toxicity. (From Kuhlman JE, Teigen C, Ken H, et al: Amiodarone pulmonary toxicity: CT findings in symptomatic patients. *Radiology* 177:121-125, 1990.) *B*, High-density consolidation in the right middle lobe in this patient was the result of metastatic pulmonary calcification of chronic renal failure in an area of pneumonia. (From Kuhlman JE, Ren H, Hutchins GM, Fishman EK: Fulminant pulmonary calcification complicating renal transplantation: CT demonstration. *Radiology* 173: 459-460, 1989.)

Figure 27-62. A and B, CT findings in a patient with silicosis. The diffuse profusion of micronodules is caused by silicosis. (From Kuhlman JE: CT of diffuse lung disease. *Appl Radiol* 20:17-21, 1991.)

Figure 27-63. A-C, CT evaluation of pneumoconiosis. Chest film and CT scan in another patient with silicosis show conglomerate masses with surrounding emphysema, scarring, and upper lobe distribution of disease. CT also reveals many small subpleural micronodules and calcifications (arrows) and calcified mediastinal and hilar nodes.

plaques, pleural thickening, and pleural calcifications, all of which are important markers of asbestos exposure (Fig. 27-63). Mimics of pleural plaques on plain films, such as rib companion shadows, extrapleural fat, and prominent intercostal muscles, are readily distinguished from pleural plaques by CT examination.

CT is also helpful in evaluating other asbestos-related pleural changes, such as *rounded atelectasis*. Rounded atelectasis has a typical CT appearance that distinguishes it from an asbestos-related malignancy, such as *lung cancer* or *mesothelioma* (see "CT Signs of Focal Lung Disease" earlier and Fig. 27-23). HRCT is also used to search for evidence of interstitial fibrosis, which may indicate the presence of *asbestosis*. Findings such as thickened interlobular septa, honeycombing, and subpleural septal lines, although not specific for asbestosis, do indicate the presence of interstitial fibrosis and, when found in association with pleural plaques, are compatible with asbestos-induced parenchymal lung damage.^{3, 5, 86}

Quantification of Lung Damage

Emphysema

Quantification of lung damage is another potential application for HRCT in the management of diffuse lung dis-

ease. One such application is the assessment of the severity and extent of **pulmonary emphysema**.^{43, 63, 148}

In emphysema, destruction of the alveolar walls and the underlying elastic fiber network of the lung results in permanent enlargement of the air spaces distal to the terminal bronchiole.⁷ Involvement of the proximal portions of the acinus (the respiratory bronchioles) results in centrilobular emphysema (CLE) (Fig. 27-64), whereas enlargement of all elements, from the respiratory bronchioles to the terminal blind alveoli, results in panlobular emphysema (Fig. 27-65).⁷⁵

Emphysema is thought to result from an imbalance in the elastase/antielastase activities within the lung. Alveolar wall destruction results from proteolytic destruction by elastin whenever there is a relative increase in elastase activity in comparison to antielastase forces, such as α_1 -antitrypsin activity.^{58, 75, 79, 119, 121, 196, 199, 233, 234}

CT features of emphysema include intraparenchymal low-attenuation areas, pulmonary vascular pruning, pulmonary vascular distortion, and abnormal lung density gradients (see Figs. 27-64 and 27-65).⁵⁵ Visual grading systems as well as more sophisticated computer-generated attenuation maps of the lung can be used to grade pulmonary emphysema in both a qualitative and a quantitative fash-

Figure 27-64. Centrilobular emphysema: correlation between CT and pathology studies. A, CT scan of an inflated-fixed lung specimen demonstrates focal areas of nonperipheral low attenuation (*long arrows*) and small peripheral bullae (*short arrows*). B, Corresponding gross pathologic specimen. C, More severe centrilobular emphysema. CT of lung specimen shows more marked dilatation of the centrilobular air spaces (*arrows*) and large peripheral bullae (*arrowheads*). D, Matching gross specimen. (A-D, From Hruban RH, Mezziane MA, Zerhouni EA, et al: High-resolution computed tomography of fixed-inflated lungs: Pathologic-radiologic correlation of centrilobular emphysema. *Am Rev Respir Dis* 136:935-940, 1987.)

Figure 27-65. A and B, Panacinar emphysema. High-resolution CT findings of panacinar bullous emphysema include intraparenchymal low-attenuation areas (lung dropout), pulmonary vascular pruning and distortion, abnormally low CT attenuation of the lung, and enlarged air spaces.

ion.^{11a} These attempts to assess the extent and severity of emphysema using HRCT criteria have achieved a high degree of success, with emphysema scores correlating well with pulmonary function tests and measurements of impaired diffusing capacity.^{43, 63}

CT provides more accurate assessments of emphysema than conventional radiographs, and CT scores of centrilobular emphysema correlate well with the severity of disease demonstrated on pathologic examinations of inflated-fixed lung specimens.^{43, 75, 148, 168} HRCT has also been found to be accurate in evaluating experimentally induced emphysema in pig lungs exposed to elastase.¹⁷⁴ Increasingly, HRCT is being used to assess the extent and severity of emphysema in clinical practice as well.^{11a, 55}

Lymphangiomyomatosis

Another pulmonary disease whose severity is more accurately depicted with HRCT than with conventional radiography is lymphangiomyomatosis (LAM).^{118, 156} Patients with LAM present with symptoms of shortness of breath and dyspnea on exertion that resemble those of emphysema, but the disease occurs exclusively in women of child-bearing age. The symptoms are typically out of pro-

portion to the abnormalities seen on conventional chest films, which may be remarkably normal. In more severe cases, chest radiographs may demonstrate hyperinflation, honeycombing, irregular opacities, coarse reticulations, chylous pleural effusions, and pneumothoraces.^{38, 57, 95, 118, 156}

The HRCT appearance of LAM is usually dramatic and characterized by bilateral, diffuse involvement of the lung with thin-walled, cystic air spaces (Fig. 27-66).^{118, 156} The cystic spaces generally measure less than 0.5 cm in mild disease but can be greater than 1 cm in diameter when more than 80% of the parenchyma is involved.¹⁵⁶ Most of the spaces have identifiable walls ranging from faintly perceptible to 2 mm thick. Typically, the lung is involved uniformly, with no predilection for upper or lower lobes.

Pathologically, LAM is characterized by widespread proliferation of atypical smooth muscle cells in the bronchial tree, alveolar septa, and pulmonary and lymphatic vessels (Fig. 27-67).^{38, 57, 95} The pathogenesis of the cystic spaces seen on HRCT is not known. One theory suggests that obstruction of small airways by the proliferating smooth muscle cells causes distal air trapping and air cyst formation. Other evidence has shown there is an increased number of disrupted elastic fibers within the lungs of patients affected by LAM. Fukuda and colleagues⁵⁷ postulate

Figure 27-66. The patient is a 43-year-old woman with shortness of breath and recurrent pneumothoraces. **A**, Chest film shows hyperinflation and coarse reticulations. **The severity of the symptoms was out of proportion to the chest film abnormalities.** (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. Radiographics 13:47-75, 1993.) **B**, High-resolution CT shows extensive replacement of normal lung architecture with innumerable thin-walled, dilated, cystic air spaces that resemble severe panacinar emphysema. In fact, this patient has diffuse lymphangiomatosis.

Figure 27-67. Pathology of lymphangiomatosis. **A**, Histologic specimen shows proliferation of smooth muscle fibers in the interstitium, and alveolar septa of the lung with remodeling of normal lung architecture. **B**, Low-power view of the lung shows replacement of the lung by cystic, dilated air spaces. (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. Radiographics 13:47-75, 1993.)

Figure 27-68. A and B, Early Langerhans' cell histiocytosis involving the lung. CT shows multiple, thin-walled regular cysts (arrows) and tiny nodules (arrowheads). (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. Radiographics 13:47-75, 1993.)

that the emphysema-like lesions seen in LAM on pathologic examination result from increased elastic fiber degradation caused by an upset of the elastase/antielastase balance within the lung.

Pulmonary Langerhans' Cell Histiocytosis (Histiocytosis X, Eosinophilic Granuloma)

A lung disease whose radiographic and CT appearance resembles lymphangiomyomatosis is pulmonary Langerhans' cell histiocytosis (formerly, histiocytosis X and eosinophilic granuloma) (Figs. 27-68 to 27-71).^{70b} Langerhans' cell histiocytosis is a granulomatous disease of unknown origin that may affect the lung exclusively or may affect multiple organ systems.¹³³ It is in the spectrum of disseminated disorders, including Letterer-Siwe disease, Hand-Schüller-Christian syndrome, and eosinophilic granuloma.¹³³ Granulomas, in each case, are formed by eosinophils and cells of the monocyte-macrophage system, which are Langerhans' cells. Langerhans' cell histiocytosis

affects mostly young and middle-aged adults, who present with complaints of cough, dyspnea on exertion, and sometimes chest pain from pneumothorax (20%) or bone involvement.^{70b, 133} These patients are almost invariably (>90%) smokers.^{70b}

Findings on plain chest films include any combination of reticulation, nodules (2 to 5 mm), cysts (<1 cm), honeycombing, and emphysematous changes.^{133, 153} The upper lung zones tend to be more involved and the costophrenic angles spared. Lung volumes are usually normal but sometimes increased. This has been attributed to the opposing effects of emphysema and the cicatricial fibrosis that occurs in this disease.

HRCT demonstrates the extent and distribution of parenchymal lung damage in Langerhans' cell histiocytosis more accurately than conventional radiography.^{25, 153} HRCT findings of pulmonary Langerhans' histiocytosis include small nodules (2 to 5 mm or less), cystic air spaces (usually <1 cm), honeycombing, and changes compatible with emphysema (see Figs. 27-68 and 27-70).^{25, 153} Much of what

Figure 27-69. Histologic specimen of lung tissue affected by Langerhans' cell histiocytosis. A focus of granulomatous reaction (arrows) has created a cystic space (arrowheads) through retraction and remodeling of the lung architecture. (From Kuhlman JE, Reyes BL, Hruban KH, et al: Abnormal air-filled spaces in the lung. Radiographics 13:47-75, 1993.)

Figure 27-70. Advanced Langerhans' cell histiocytosis. A, Chest film in a 19-year-old woman with diabetes insipidus and dyspnea. A right pneumothorax and increased reticulations are present. B, High-resolution CT more clearly shows that the lung has been replaced by cystic spaces of varying sizes, some of which have coalesced into bizarre shapes (arrow). (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

appears to be reticulation and emphysema on plain films can be shown to be discrete cystic air spaces with definable walls on HRCT.²⁵ Sometimes several cystic spaces coalesce to form bizarrely shaped air spaces on CT scans. CT also demonstrates more of the smaller (<2 mm) nodules that are frequently not visible on plain radiographs (see Fig. 27-68).²⁵ These small nodules are more common in the early stages of the disease and tend to spare the lung bases and predominate in the upper lung zones.^{70b} With progression, cystic changes take over the lung. Bullae, cavitating nodules, and traction bronchiectasis are also features of Langerhans' cell histiocytosis that can be appreciated on CT examination.^{25, 153}

The mechanism by which cystic spaces form in pulmonary Langerhans' cell histiocytosis is uncertain.⁸⁷ Central necrosis of granulomatous nodules may produce the thin-walled cavities seen in early pulmonary Langerhans' histiocytosis (see Fig. 27-69). Others have postulated a check-valve obstruction of bronchioles leading to dilatation of

distal airspaces. Another theory suggests that progressive fibrosis occurs around areas of bronchiolar inflammation and granuloma formation. This leads to retractile, paracatricial emphysema in these peribronchiolar areas with disruption and remodeling of the elastic fiber network that eventually produces a honeycomb lung (see Fig. 27-71).^{70b, 87}

Tracheolaryngeal Papillomatosis

Tracheolaryngeal papillomatosis is another rare disease whose lung dissemination is best documented and assessed with CT evaluation. Laryngeal papillomatosis results from an infection by the human papillomavirus that is transmitted from mother to child during birth. Papillomas grow in the upper airways of the child and consist of cauliflower-like lesions with fibrovascular cores or stalks covered by a stratified squamous epithelium.⁴⁷

In the juvenile tracheolaryngeal form of papillomatosis,

Figure 27-71. Advanced Langerhans' cell histiocytosis. Gross lung specimen shows diffuse replacement of the lung by cystic spaces.

Figure 27-72. CT features of juvenile tracheolaryngeal papillomatosis. Several thin, delicate-walled cystic air spaces are seen (arrows) on the chest film (A) and the CT scan (B) in this 12-year-old boy with upper airway papillomas. (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

the disease extends inferiorly into the tracheobronchial tree (5% of cases) and into the lung parenchyma (1% of cases) (Figs. 27-72 to 27-74).⁹⁴ When the lung parenchyma is involved, round nodules, either solid or cystic, may be seen on chest radiographs or CT (see Fig. 27-72). The small cystic lesions eventually enlarge to several centimeters in diameter, with varying wall thickness (see Fig. 27-73).^{89, 94} On CT scans, the lesions are widely distributed but with a predilection for the lower lobe and the posterior.

The pathogenesis of lung involvement in tracheolaryngeal papillomatosis is believed to be via aerial dissemination. Small fragments of papillomatous tissue break off

from the upper airways (secondary to bronchoscopy, surgery, tracheostomy) and travel through the major bronchi, where they lodge in the distal small airways causing obstruction and distal air trapping. There, the papilloma fragments enlarge centrifugally and grow along the expanded air spaces. Eventually the papillomatous masses undergo cavitation to form larger cavitary air spaces that are lined by stratified squamous epithelium (see Fig. 27-74).^{89, 94}

Figure 27-73. Advanced tracheolaryngeal papillomatosis. CT shows extensive cavitary spaces that have a branching and clustered appearance reminiscent of cystic bronchiectasis. The walls are thick and irregular. (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

Figure 27-74. Pathology of tracheolaryngeal papillomatosis. A large cavitary space (arrows) is lined with verrucous papillomatous tissue. The adjacent bronchus is also involved (arrow-head). Papilloma fragments lodge in distal airways, where they grow along the terminal air spaces. Cavitary spaces form when papillomatous tissues cause bronchiolar obstruction or when papillomatous tumor masses necrose. (From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

Monitoring Disease Activity, Complications, and Response to Therapy

Interstitial Pulmonary Fibrosis

Interstitial pulmonary fibrosis may be idiopathic (idiopathic pulmonary fibrosis [IPF], fibrosing alveolitis, and UIP) or may be associated with a number of other disease entities, including collagen vascular disorders (rheumatoid arthritis, polymyositis, lupus, scleroderma, and mixed connective tissue-overlap syndromes), asbestosis, drug toxicity, sarcoidosis, end-stage Farmer's lung, and Langerhans' cell histiocytosis, among others.

CT is useful in diagnosis of IPF in symptomatic patients with nonspecific abnormalities on chest radiographs and in monitoring the disease status in these patients.^{155, 159, 211, 215, 227-230} CT visual scoring systems of IPF correlate better than plain film findings with clinical and functional assessments of disease severity.^{155, 159, 211, 215, 227-230}

In the early stages of IPF, subpleural ground-glass infiltrates and crescentic densities are identified in the peripheral aspects of the lungs and posterior segments of the lower lobes bilaterally. Later, these subpleural crescentic densities evolve into reticulation and subpleural honeycombing (Figs. 27-75 and 27-76). As honeycombing and fibrosis progress, traction bronchiectasis develops.^{155, 159, 211, 215, 227-230} Some honeycomb cysts enlarge to great size as

the lung parenchyma is gradually replaced and remodeled by progressive fibrosis.

CT can be used quite effectively to monitor the progression of IPF and its response to treatments such as corticosteroids. The significance of ground-glass opacities in IPF remains controversial. Some authors believe that the presence of such opacities on CT scans in cases of IPF indicates the presence of active alveolitis that may respond to treatment. Other authors have challenged this notion with pathologic correlation studies showing that ground-glass opacities can correspond to areas of alveolitis or to areas of fine fibrosis. The presence of honeycombing on CT scans, however, is a fairly reliable indication of irreversible lung damage.^{155, 159}

Adult Respiratory Distress Syndrome

The patient with ARDS generally requires high positive-pressure mechanical ventilation and is at high risk for development of barotrauma in the form of interstitial emphysema, subpleural air cyst formation, pneumothorax, and pneumomediastinum (see Figs. 27-23 and 27-24).²³¹ Although CT has not been used extensively in patients with ARDS, it may play a role in the evaluation of acute and long-term complications in this setting.^{45a, 148a} CT assessments of disease severity and their prognostic implications are currently under investigation by several authors (Fig. 27-77).^{21, 45a, 66, 140, 151, 180, 212, 220}

Figure 27-75. Idiopathic pulmonary fibrosis. A and B, High-resolution CT shows subpleural reticulations and small air cysts (arrowheads) ranging in size from 2 to 10 mm. Honeycombing is more severe in the periphery of the lung. C, Autopsy specimen shows many subpleural air cysts (arrows) in a subpleural distribution with extensive fibrosis and lung remodeling. The transition is abrupt between central normal-appearing lung and the peripheral honeycombing. (B and C, From Kuhlman JE, Reyes BL, Hruban RH, et al: Abnormal air-filled spaces in the lung. *Radiographics* 13:47-75, 1993.)

Figure 27-76. A and B, Interstitial pulmonary fibrosis associated with polymyositis. High-resolution CT shows reticulation and honeycombing in the periphery of the lung and in the lung bases, more severe on the right than on the left. Note "traction" bronchiectasis due to interstitial fibrosis.

Figure 27-77. A and B, High-resolution CT of adult respiratory distress syndrome (ARDS) and its complications. Postpartum pneumonia and ARDS developed in a 17-year-old girl. Bilateral "ground-glass" infiltrates compatible with a diagnosis of ARDS are evident on CT scanning. Large extra-alveolar air cysts have developed. CT shows that these air cysts have no discernible walls and are located in the subpleural and basal regions of the lung. Bilateral chest tubes are in place for complicating pneumothoraces. Subcutaneous emphysema is present.

The pathophysiology of barotrauma-related complications in ARDS was first examined by Macklin and Macklin¹²⁹ and then further elucidated by Westcott and Cole.²³¹ The process begins with rupture of weaker alveoli along the margins of the interlobular septa and bronchovascular structures as a result of increased airway pressures. Air then dissects along the interlobular septa and along the perivascular spaces, producing interstitial emphysema. Interstitial air may then rupture into the pleural space causing pneumothorax or into the mediastinum causing pneumomediastinum. Or air may collect in extra-alveolar spaces within the interstitium, forming large air cysts. These air cysts typically are found in the lung bases and subpleural zones adjacent to the diaphragm or mediastinum. They may enlarge to great size, causing respiratory and circulatory compromise, and they may be mistaken for loculated pneumothoraces.^{129, 231}

On CT scans, subpleural air cysts associated with ARDS appear as air spaces with no definable walls (see Fig. 27-77).²¹² They typically expand into the fissures or subpulmonic zones and compress adjacent lung parenchyma as they enlarge. Although a CT scan is not as easy to obtain as a portable chest film in critically ill, ventilator-dependent patients, CT is more accurate in identifying and localizing complications of barotrauma, such as pneumothoraces, pneumomediastinum, and subpleural air cysts. This may become important in those select patients who are not responding to treatment or who deteriorate suddenly for unclear reasons. For example, what may appear to be an appropriately placed chest tube on a portable supine chest radiograph may be found to be inadequate in location on CT scans.

In addition, a few investigators have begun to correlate patient outcome in ARDS with the extent and severity of pulmonary infiltrates and complications as graded by CT.^{21, 66, 140, 151, 180, 212, 220} Further study is necessary to determine whether CT findings of ARDS are reliable prognostic indicators.

Sarcoidosis

CT is used extensively to identify, stage, and monitor patients with pulmonary sarcoidosis, a disease of unknown origin that is characterized pathologically by the presence of noncaseating granuloma.²¹⁹ The lung and the intrathoracic lymph nodes are the most commonly affected organs of the body, and thoracic complications account for most of the morbidity and mortality caused by this disease.¹⁷⁸ Although only 60% of patients with sarcoidosis demonstrate chest film abnormalities, histologic evidence of granulomatous disease is almost always present on biopsy specimens taken from the lung.¹⁷⁸

CT is more accurate than conventional radiography in detecting subtle areas of parenchymal involvement and in delineating the full extent of lung disease caused by sarcoidosis.^{69, 108, 191, 208} CT features of pulmonary sarcoidosis include thickening of the interlobular septa, reticulonodular disease, multinodular disease, mixed infiltrates, and masslike consolidations. In pulmonary sarcoidosis, the noncaseating granulomas have a propensity for forming in association with the lymphatics of the interstitial tissues in the peribronchial, perivascular, and subpleural spaces as

well as in the interlobular septa. These granulomas produce the reticulonodular infiltrates seen on CT scans, which may appear predominantly linear or nodular depending on the size of the granulomas and the amount of fibrosis that is present (Fig. 27-78). Granulomas that form along the interlobular septa can produce an appearance resembling the beaded septum sign seen in lymphangitic carcinomatosis.^{108, 178}

Pulmonary involvement in sarcoidosis is usually bilateral, although it may be asymmetrical. Multinodular disease may have several distributions; for example, tiny nodules, 1 to 3 mm in size, distributed evenly throughout the lung in a miliary pattern, or large, coarser nodules that are more varied in size and more unevenly scattered. Subpleural nodules, septal nodules, and perihilar peribronchovascular nodules are typical of sarcoidosis. Mixed patterns with reticulation, thickening of the interlobular markings, fibrosis, and pleural thickening may also be seen.^{69, 108, 191, 208}

Occasionally, sarcoidosis presents as multiple, round, masslike consolidations on chest films and CT. The masses often demonstrate air-bronchograms, and this form of sarcoidosis has been called *alveolar* or *acinar* sarcoid (Fig. 27-79).^{60, 108, 122, 191, 218} These masses, however, do not represent true air space filling in the sense that a pneumonia would; rather, the masses represent numerous granulomas that have coalesced within the interstitium, forming massive conglomerates that compress the surrounding air spaces.

Pathologically, pulmonary sarcoidosis begins as an acute alveolitis followed by a phase of granuloma formation within the lung interstitium.²¹⁹ In most cases, the disease stabilizes at this stage, leaving the patient with persistent granulomas in the lung, or the lung disease resolves completely. In 20% of patients, however, the disease progresses.¹⁷⁸ With more advanced disease, findings of pulmonary fibrosis dominate the CT picture. Progressive fibrosis and architectural distortion lead to honeycombing, fibrocystic changes, bullae, traction bronchiectasis, and retraction of the pulmonary hila (Fig. 27-80). The upper lung zones are more severely affected, and evidence of secondary pulmonary hypertension and cor pulmonale is frequently seen. Fibrotic conglomerate masses reminiscent of those seen in silicosis may also develop in advanced disease.^{69, 108}

True cavities lined by noncaseating granulomas are extremely rare (<0.6%) in sarcoidosis.^{178, 191} Most apparent cavities are the result of fibrocystic disease and bullae that develop in advanced disease, and they are lined by fibrous tissue, not granulomas. Superimposed infection of fibrocystic spaces, particularly with *Aspergillus*, is a frequent complication of sarcoidosis and accounts for significant morbidity and mortality.

In the patient with advanced sarcoidosis and hemoptysis, CT is useful in detecting or confirming the presence of complicating aspergillomas, particularly when the chest radiograph is difficult to interpret because of extensive disease and fibrosis (Fig. 27-81).^{69, 108, 208} CT scans obtained in the supine and prone positions usually demonstrate movement of mycetomas within cystic spaces. Superimposed bacterial infections may also complicate fibrocystic spaces in sarcoidosis, and there is a higher incidence of TB in sarcoid patients than in the population as a whole.¹⁷⁸

Figure 27-78. The many CT appearances of sarcoidosis. A–C, Bulky paratracheal adenopathy and small subpleural nodule (*arrow*). D, Tiny miliary interstitial nodules. Note the subcarinal adenopathy (*arrow*). E, Slightly larger nodules scattered throughout lung.

Figure 27-78. *Continued.* F, Fine reticulonodular markings. G, Linear interstitial markings. H and I, Larger irregular opacities. J, Conglomerate masses (arrows) and calcified mediastinal nodes. (D, E, F, and J, From Kuhlman JB, Fishman EK, Zerhouni EA, et al: The computed tomographic spectrum of thoracic sarcoidosis. *Radiographics* 9:449-466, 1989.)

Figure 27-79. A and B, Alveolar sarcoid. CT shows round masslike consolidations with air-bronchograms. Note hilar adenopathy.

Other thoracic complications of sarcoidosis include extension of the inflammatory, fibrotic process into the mediastinum, resulting in fibrosing mediastinitis. On CT scans, abnormal fibrotic tissue can be seen to narrow and obstruct the mainstem bronchi, mediastinal vessels, and pulmonary vessels (Fig. 27-82).^{69, 108}

Lymphadenopathy is even more common than parenchymal lung disease in patients with sarcoidosis, and CT is superior to chest radiography for delineating the full extent of lymphadenopathy (Fig. 27-83).^{69, 178, 191} Paratracheal and hilar adenopathy are typical of sarcoidosis, but CT also may demonstrate adenopathy in the anterior mediastinum, axilla, internal mammary chain, and below the diaphragm.^{69, 191, 192}

The major differential diagnosis to consider when adenopathy is seen in these locations is lymphoma, and definitive diagnosis usually requires tissue confirmation. Certain CT patterns of nodal involvement, however, favor a diagnosis of sarcoidosis. Symmetrical paratracheal and hilar adenopathy, especially when accompanied by reticulonodular

infiltrates, is suggestive of sarcoidosis in the non-HIV-positive patient.⁶⁹

In contrast to adenopathy caused by neoplastic disorders, enlarged lymph nodes resulting from sarcoidosis tend to remain discrete and maintain their rounded nodal shape, rather than coalescing into amorphous nodal masses.^{69, 108} Calcifications within hilar and mediastinal nodes are common in sarcoid, which is one of the diseases that can produce eggshell calcifications in lymph nodes along with TB, fungal infections, and silicosis.

In clinical practice, CT examination of the patient with sarcoidosis is an integral part of the evaluation process at all stages of the disease. Indications for CT evaluation include establishing and confirming the diagnosis, staging the disease, monitoring disease activity and progression, assessing treatment response, and detecting and evaluating complications.¹⁰⁸

Patients with chest film abnormalities and possible sarcoidosis may benefit from further characterization of their pulmonary disease by CT. CT also serves as a road map

Figure 27-80. A and B, Advanced sarcoid with lung fibrosis, honeycombing, and extensive fibrocystic changes.

Figure 27-81. Complication of sarcoidosis—mycetoma formation. A, Chest film shows extensive upper lobe disease and fibrosis resulting from sarcoidosis. B-D, CT reveals that at least five mycetomas are present (arrows). (A and B, From Kuhlman JE, Fishman EK, Zerhouni EA, et al: The computed tomographic spectrum of thoracic sarcoidosis. *Radiographics* 9:449-466, 1989.)

Figure 27-82. Fibrosing mediastinitis resulting from sarcoidosis. A, CT shows abnormal soft tissue infiltration of the mediastinal fat with amputation of the left pulmonary artery (arrow). Enlarged internal mammary nodes as well as lung disease and a left pleural effusion are present. B, A ventilation-perfusion scan shows ventilation but no perfusion to the left lung. (From Kuhlman JE, Fishman EK, Zerhouni EA, et al: The computed tomographic spectrum of thoracic sarcoidosis. *Radiographics* 9:449-466, 1989.)

Figure 27-83. CT evaluation of sarcoidosis to determine the extent of adenopathy. *A*, Bulky anterior mediastinal and right paratracheal adenopathy (arrows). *B*, Bilateral hilar and subcarinal adenopathy. (From Kuhlman JE, Fishman EK, Zerhouni EA, et al: The computed tomographic spectrum of thoracic sarcoidosis. *Radiographics* 9:449-466, 1989.)

for planning biopsy procedures, localizing the best sites for transbronchial lung biopsy, percutaneous biopsy, and nodal sampling. Patients with known sarcoidosis also benefit from CT evaluation when atypical radiographic findings require further explanation or when complications are suspected but have not been detected by conventional radiography.^{69, 108}

Summary

CT remains an adjunct to the conventional chest radiograph in the evaluation of non-neoplastic lung diseases. As an adjunct, however, CT is an important, indispensable asset. When combined with HRCT techniques and the emerging fast scanning capabilities of spiral, multidetector, and ultrafast electron beam CT, CT has become a powerful tool for detecting, characterizing, and quantifying non-neoplastic diseases of the lung.

Primary Pulmonary Neoplasms

Jeremy J. Erasmus, H. Page McAdams,
Santiago E. Rossi

Although most primary pulmonary tumors are carcinomas, a large histologic spectrum of benign and malignant tumors of the lung exists. This chapter reviews the more common neoplasms according to the classification proposed by the World Health Organization (WHO) (Table 28-1) and emphasizes the radiologic manifestations of these neoplasms and the use of imaging in diagnosis and management.

Malignant Neoplasms of the Lung *Epithelial Tumors*

Lung Cancer

Epidemiology

Lung cancer is a common malignancy. The American Cancer Society (ACS) estimated that 169,500 new cases would be diagnosed in the United States in the year 2001.^{4,4a} The number of new cases in men, however, decreased from a high of 86.5 per 100,000 in 1984 to 69.1 in 1997.²⁵⁷ The incidence of lung cancer in women has continued to increase since the 1960s, and in 1997 although the rate of increase slowed in the 1990s, 43.1 per 100,000 new cases occurred in 1997. The annual mortality rate in men decreased during the 1990s, whereas the rate in women continues to increase.²⁵⁷ Lung cancer remains the leading cause of cancer-related deaths in both men and women in the United States, and the ACS estimated that it would account for 28% of all cancer deaths in the year 2001.^{4a}

Etiology

The strongest risk factor for the development of lung cancer is cigarette smoking; an estimated 85% to 90% of lung cancers in men and 80% in women have been attributable to smoking.^{4, 9, 58, 234, 237} The length of time and the number and type of cigarettes smoked are directly related to the risk of lung cancer.^{61, 196, 235} Squamous cell and small-cell carcinomas have the highest association with smoking, whereas adenocarcinomas are the predominant cell type in nonsmokers.⁶¹ The change in smoking habits (use of filter tips, decrease in tar yield), however, has been postulated to account for the recent increase in incidence of adenocarcinomas in cigarette smokers.^{61, 228, 262}

Involuntary smoke exposure (passive smoking) is generally considered to be associated with an increased risk

of lung cancer, although the numerous variables in the epidemiologic data make this difficult to conclude with certainty.^{4, 185, 196, 230, 237} Spousal smoking has, however, been estimated to increase the lung cancer risk by 20% in women who have never smoked.²³

Environmental and occupational exposures to particulate and chemical substances are additional risk factors.^{212, 243} Exposure to the naturally occurring radioactive gas radon, both in homes and in mines, is the most important risk factor after cigarette smoking.^{152, 196, 212, 245} It is estimated that 7000 to 30,000 lung cancer deaths occur annually in the United States as a result of residential exposure to radon.²⁴⁵

Asbestos is a carcinogen, and although there is an unequivocal association between lung cancer and asbestos exposure, the magnitude of the risk is frequently overestimated (most cohort studies show less than a twofold increase in risk).⁷⁴ Although the risk of lung cancer in workers exposed to asbestos may depend on individual occupational exposure characteristics (i.e., duration, concentration, and fiber type), the increased risk may be largely limited to those with radiologic evidence of asbestosis or to cigarette smokers.^{74, 188, 236, 252} It has been estimated that as many as 33% of lung cancers that occur in smokers exposed to asbestos are the result of the synergistic effect of the two carcinogens.⁵³

Additional risk factors for development of lung cancer include exposure to arsenic, chloromethyl ethers, chromium, isopropyl oil, mustard gas, nickel, beryllium, chloroprene, vinyl chloride, and various smelting by-products such as lead and copper.²¹² Other factors, such as focal or diffuse pulmonary fibrosis and ionizing radiation, have been reported to increase the risk of lung cancer. Epidemiologic data, however, do not clearly establish a cause-and-effect relationship, except in some patients with Hodgkin's disease treated with radiation.¹²⁰ Finally, although not clearly understood, genetic susceptibility to lung cancer may be involved in a small number of cases.^{10, 54, 177, 196}

Histologic Classification

Lung cancer is divided by the WHO Classification into two major histologic categories: *non-small-cell* lung carcinoma (NSCLC) and *small-cell* lung carcinoma (SCLC) (see Table 28-1).²²⁷ NSCLC is further subdivided into histologic variants such as squamous cell carcinoma, adenocarcinoma, and large-cell carcinoma, according to the most differentiated portion of the tumor. Many tumors,

Table 28–1. Histologic Classification of Lung Tumors

I. Epithelial Tumors	
A. Benign	
Papillomas	
Adenomas	
B. Malignant	
Squamous cell carcinoma	
Variants: papillary, clear cell, small-cell, basaloid	
Adenocarcinoma	
Acinar adenocarcinoma	
Papillary adenocarcinoma	
Bronchioloalveolar carcinoma	
Solid adenocarcinoma with mucin	
Adenocarcinoma with mixed subtypes	
Variants: fetal, clear cell, signet-ring, colloid	
Large cell carcinoma	
Variants: clear cell, large-cell neuroendocrine, combined large-cell neuroendocrine, basaloid, lymphoepithelioma-like carcinomas	
Adenosquamous carcinoma	
Small-cell carcinoma	
Variant: combined small-cell carcinoma	
Carcinomas with pleomorphic sarcomatoid or sarcomatous elements	
Carcinomas with spindle and/or giant cells (pleomorphic carcinoma, spindle cell carcinoma, giant cell carcinoma)	
Carcinosarcomas	
Pulmonary blastoma	
Carcinoid tumor	
Typical carcinoid	
Atypical carcinoid	
Carcinomas of salivary-gland type	
Mucoepidermoid carcinoma	
Adenoid cystic carcinoma	
II. Mesenchymal Tumors	
Primary pulmonary sarcomas	
Vascular sarcomas (angiosarcoma, epithelioid, emangioendothelioma)	
Spindle cell sarcomas (malignant fibrous histiocytoma, hemangiopericytoma, fibrosarcoma, leiomyosarcoma, synovial sarcoma)	
III. Lymphoproliferative Disorders	
Lymphoid interstitial pneumonia	
Nodular lymphoid hyperplasia	
Low-grade marginal-zone B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT)	
Lymphomatoid granulomatosis	
IV. Miscellaneous Tumors	
Hamartoma	
Granular cell tumors	
Sclerosing hemangioma	
Clear cell tumor	
V. Tumor-like Lesions	
Hyalinizing granuloma	
Amyloid tumor	

Modified from Travis WD, Colby TV, Corrin B, et al: *Histological Typing of Lung and Pleural Tumors*, 3rd ed. Berlin, Springer-Verlag, 1999.

however, are composed of more than one histologic type and are classified as *combined tumors*. Additionally, NSCLC are graded as *well-differentiated*, *moderately differentiated*, or *poorly differentiated* according to the least differentiated feature.²²⁷ Exceptions to this grading classification are pleomorphic carcinoma, carcinosarcoma, and SCLC, all of which are poorly differentiated tumors.²²⁷

Squamous Cell Carcinoma. Squamous cell carcinomas have been decreasing in relative incidence and now

constitute 25% of all lung cancers. They typically occur in central bronchi and frequently manifest as postobstructive pneumonia or atelectasis (Fig. 28–1).^{189, 202, 225} Mucoid impaction, bronchiectasis, and hyperinflation are uncommon radiologic manifestations (Fig. 28–2).^{202, 225, 258}

Approximately one third of squamous cell carcinomas occur beyond the segmental bronchi and usually range in size from 1 to 10 cm (Fig. 28–3).^{202, 225} Squamous cell carcinomas are more likely to cavitate than the other histologic cell types of lung cancer.²⁰² Cavitation occurs in 10% to 30% and is more common in large peripheral masses and poorly differentiated tumors.²²⁵ Cavitation is typically eccentric with thick, irregular walls, although thin walls may occur in rare circumstances.²⁰² Most squamous cell carcinomas grow slowly, and extrathoracic metastases tend to occur late.²⁰²

Adenocarcinoma. Adenocarcinomas have increased in incidence and are now the most common cell type, compos-

Figure 28–1. Squamous cell lung cancer seen as a central endobronchial mass. A, Posteroanterior chest radiograph shows complete atelectasis of the right upper lobe. Convexity in the lower portion of the atelectatic lung (arrows) is the result of a large central mass. B, CT confirms the large central mass in the region of the right upper lobe bronchus.

Figure 28-2. Squamous cell lung cancer with obstructive hyperinflation of the left upper lobe. A and B, CT scan shows hyperlucency of the left upper lobe and an endobronchial mass that completely occludes the left upper lobe bronchus (arrow in B).

ing 25% to 30% of all lung cancers.¹⁸⁹ Adenocarcinomas typically manifest as peripheral, solitary pulmonary nodules. Nodules can have an irregular or spiculated margin as a result of parenchymal invasion and an associated fibrotic response (Fig. 28-4).^{202, 225} Lymphangitic carcinomatosis, although uncommon at presentation, occurs more frequently with adenocarcinomas and typically manifests radiologically as thickening of interlobular septa or multiple small pulmonary nodules (Fig. 28-5).¹²⁵ Intrathoracic metastases to hilar and mediastinal nodes are present in 18% to 40% and in 2% to 27% of patients, respectively, and tend to occur more often with more centrally located adenocarcinomas.^{189, 225, 261}

Bronchioloalveolar cell carcinoma (BAC), a subset of adenocarcinoma, constitutes 0.5% to 10% of all lung can-

cers.⁴⁹ BAC can be either solitary or multifocal at the time of initial presentation. To explain this difference, it has been proposed that the origin of BAC is either *monoclonal* (with multifocality due to dissemination by aerosolization, intrapulmonary lymphatics, and intra-alveolar growth) or *polyclonal* (with multifocality due to de novo tumor growth at multiple sites).^{11, 88, 128, 138, 202}

The most common radiologic manifestation is a peripheral, solitary nodule that can remain stable in size for many years (Fig. 28-6).^{42, 87, 108, 225} Although cavitation in these nodules is uncommon, the occurrence of multiple small, focal, low-attenuation regions (pseudocavitation) or air-bronchograms within the nodule can occasionally be useful in suggesting the diagnosis.^{108, 162, 251, 273} The diffuse form may present as multiple nodules (usually small, occasion-

Figure 28-3. Squamous cell lung cancer manifesting as a peripheral mass. A, Posteroanterior chest radiograph shows a large lobular mass in the right upper lobe. Note the absence of hilar or mediastinal adenopathy. B, CT confirms the large lobular mass in the right upper lobe.

Figure 28-4. Adenocarcinoma manifesting as a pulmonary nodule. CT scan shows a nodule in the apical segment of the right upper lobe. The spiculated margin is typical of lung cancer.

Figure 28-5. Adenocarcinoma of the lung appearing as lymphangitic carcinomatosis. *A* and *B*, Thin-section CT scan shows thickening of bronchial walls and interlobular septa (arrowheads) in the left lung. Nodularity of the septa is suggestive of malignancy.

Figure 28-6. Bronchioloalveolar cell carcinoma seen as a solitary pulmonary nodule. *A*, Posteroanterior chest radiograph shows a nodule (arrow) in left upper lobe. *B*, CT scan reveals a spiculated margin suggestive of malignancy.

Figure 28-7. Bronchioloalveolar cell carcinoma (BAC) manifesting as multiple pulmonary nodules. CT shows small, well-marginated pulmonary nodules with central areas of cavitation (the “Cheerio” sign of BAC).

ally cavitary), “ground-glass” opacities, and opacities resembling pneumonia (Figs. 28-7 and 28-8).^{2, 11, 42, 50, 87, 138, 202} Most patients with the diffuse form of BAC have a combination of these findings (Fig. 28-9).² Hilar and mediastinal adenopathy and pleural effusions are uncommon.^{42, 87, 162, 202}

Large-Cell Carcinoma. These lesions make up 10% to 20% of all lung cancers.^{58, 202} Most are peripheral, poorly

marginated masses greater than 7 cm in diameter (Fig. 28-10).^{21, 58, 189, 201, 202, 225} Although growth is typically rapid, cavitation is uncommon.²⁰¹ Hilar and mediastinal adenopathy occurs in up to one third of patients at presentation, and early extrathoracic metastases are common.^{58, 201, 202, 225}

Small-Cell Lung Cancer. SCLCs compose 20% to 25% of all lung cancers.⁵⁸ The primary tumor is typically small, is central in location, and is associated with marked hilar and mediastinal adenopathy and distant metastases to liver, bone marrow, adrenals, and brain (Figs. 28-11 and 28-12).^{58, 189, 225, 233} Pleural effusions occur in 5% to 40% of patients.^{176, 202, 253} Approximately 5% of SCLCs manifest as small, peripheral, solitary pulmonary nodules without intrathoracic adenopathy, disseminated extrathoracic disease, or pleural effusions.^{75, 233}

Clinical Manifestations

Most patients are in their fifth and sixth decades of life and are symptomatic at presentation.^{5, 58, 196} Symptoms are variable and depend on the local effects of the primary mass, the presence of regional or distant metastases, and the coexistence of paraneoplastic syndromes.

Central endobronchial carcinomas can manifest as fever, dyspnea, hemoptysis, and cough.⁵ Cough productive of copious amounts of watery sputum (bronchorrhea) typically also occurs in patients with BAC and extensive parenchymal disease, but this is rarely seen.⁵⁰ Symptoms that can occur as a result of local growth and invasion of adjacent nerves, vessels, and mediastinal structures include:

1. Chest pain (peribronchial nerve involvement); vocal cord paralysis and hoarseness (recurrent laryngeal nerve involvement) (Fig. 28-13); dyspnea due to diaphragmatic paralysis (phrenic nerve involvement) (Fig. 28-14); Horner’s syndrome—ptosis, mycosis, anhidrosis (sympathetic chain and stellate ganglion involvement by superior sulcus tumors) (Fig. 28-15).¹⁷²
2. Facial swelling, headaches, enlarged collateral chest wall vessels (superior vena cava obstruction).¹⁷²
3. Dysphagia (esophageal invasion).

Figure 28-8. Bronchioloalveolar cell carcinoma appearing as homogeneous opacities mimicking pneumonia. A, Posteroanterior chest radiograph shows diffuse, bilateral, homogeneous pulmonary opacities. Surgical clips are present in the medial aspect of the left hemithorax because of prior partial pulmonary resection. B, CT confirms the diffuse bilateral pulmonary consolidation and reveals a small left pleural effusion.

Figure 28–9. Bronchioloalveolar cell carcinoma seen as nodules and consolidation. CT scan shows an opacity in the right lower lobe resembling pneumonia and a small nodule (*arrow*). Numerous small, well-circumscribed nodules were scattered throughout both lungs (not shown).

Figure 28–10. Large-cell lung cancer manifesting as a large cavitory mass. *A*, Posteroanterior chest radiograph shows a large, lobular mass in the right upper lobe. Cavitation is present with an air-fluid level in the upper aspect of mass. *B*, CT shows a well-circumscribed mass with eccentric cavitation and thick walls. Note the nonenlarged, paratracheal and low left paratracheal lymph nodes (*arrowheads*).

Figure 28-11. Small-cell lung cancer appearing as intrathoracic adenopathy. *A*, Posteroanterior chest radiograph shows marked right hilar adenopathy. *B* and *C*, CT scan shows marked right hilar and subcarinal adenopathy and reveals a small primary malignancy in the right upper lobe (in *C*).

Figure 28-12. Small-cell lung cancer seen as intrathoracic adenopathy and atelectasis. *A*, Posteroanterior chest radiograph shows complete atelectasis of the right upper lobe with mild convexity of the distal aspect of the minor fissure (arrows) caused by an underlying right hilar mass. *B*, CT scan confirms marked hilar and mediastinal adenopathy and reveals occlusion of the right upper lobe bronchus.

Figure 28-13. Small-cell lung cancer in a 76-year-old man presenting with hoarseness caused by involvement of the recurrent laryngeal nerve. *A*, Posteroanterior chest radiograph shows an aortopulmonary window mass. *B*, CT reveals mediastinal invasion with an extension of the mass into the aortopulmonary window (the anatomic location of recurrent laryngeal nerve).

Figure 28-14. Small-cell lung cancer in a 50-year-old woman with diaphragmatic paralysis resulting from phrenic nerve involvement. *A*, Posteroanterior chest radiograph shows a large lobular mass in the left lower lobe and elevation of the left hemidiaphragm. *B*, CT reveals a necrotic mass in the left lower lobe and mediastinum (arrows) in the anatomic location of the phrenic nerve.

Figure 28-15. Non-small-cell lung cancer in a 54-year-old man with Pancoast's tumor and with a 2-month history of neck pain. *A*, Posteroanterior chest radiograph shows a left apical mass with destruction of the first rib (arrowheads). *B*, CT confirms the left superior sulcus tumor and destruction of the left first rib.

Many patients present with symptoms related to extra-thoracic metastases, most commonly bone pain or central nervous system (CNS) abnormalities.^{5, 100} Clinical signs and symptoms can also be caused by tumor excretion of a bioactive substance, or hormone, or as a result of an autoimmune phenomenon.^{5, 171} These paraneoplastic syndromes occur in 10% to 20% of lung cancer patients and are usually associated with SCLC.^{5, 22, 124, 220} Antidiuretic and adrenocorticotropin hormones are the more frequently excreted hormones and can result in hyponatremia and serum hypo-osmolality and in Cushing's syndrome (central obesity, hypertension, glucose intolerance, plethora, hirsutism), respectively.^{27, 40, 121, 157, 199, 202} Other hormones that can be elevated are calcitonin; growth hormone; human chorionic gonadotropin; and, rarely, prolactin and serotonin.¹²⁴

Neurologic paraneoplastic syndromes (Lambert-Eaton myasthenic syndrome, paraneoplastic cerebellar degeneration, paraneoplastic encephalomyelitis, paraneoplastic sensory neuropathy) are rare and are usually associated with SCLC.^{25, 26, 28, 33, 113, 179} The neurologic symptoms typically

precede the diagnosis of lung cancer by up to 2 years, are incapacitating, and progress rapidly, although improvement can occur after treatment of the lung cancer.^{33, 113}

Miscellaneous paraneoplastic syndromes associated with lung cancer include acanthosis nigricans, dermatomyositis, disseminated intravascular coagulation, and hypertrophic pulmonary osteoarthropathy (HPO). Of these, HPO is the most common, occurring in up to 17% of patients with adenocarcinoma (Fig. 28-16).¹⁴³

Radiologic Evaluation

Although imaging has an important role in the diagnosis, staging, and monitoring of patients with lung cancer, the role of imaging in screening for malignancy is not clearly defined.

Screening

Because diagnosis of lung cancer at an early stage is associated with an improved prognosis, screening has been

Figure 28-16. Non-small-cell lung cancer in an asymptomatic 64-year-old woman. *A*, CT scan shows a large right upper lobe mass. *B*, Technetium 99m (^{99m}Tc)-labeled methylene diphosphonate (MDP) bone scintigraphy shows linear areas of increased radiotracer uptake in the femurs and tibias. This appearance is characteristic of hypertrophic pulmonary osteoarthropathy.

advocated to detect lung cancer before clinical presentation. The ACS does not, however, recommend routine radiologic evaluation for the detection of lung cancer but instead advocates primary prevention.⁵⁹ This recommendation is based on the results of four large randomized trials undertaken in the 1970s, which evaluated the utility of chest radiographs and sputum cytology in lung cancer screening. These trials showed that screening improved long-term survival rates without reducing mortality (considered the best evidence that screening is effective, as it is not affected by lead-time bias, length bias, and overdiagnosis bias).^{12, 60, 105, 151, 218}

A reanalysis of the data from these trials has suggested some justification for the use of chest radiography in lung cancer screening.^{216, 217} Additionally, because of the concerns about design and methodology of the previous trials, together with improved detection of small lung cancers using computed tomography (CT), there has been a renewed interest in reevaluating screening. Consequently, new multi-institutional screening studies in the United States, supported by the National Cancer Institute as well as by other smaller trials in Japan and Germany, are being performed to reexamine the role of screening in lung cancer management.^{83, 93, 161, 207}

Diagnosis

Because most patients with lung cancer have advanced disease at presentation, diagnosis is usually not difficult. Nevertheless, 20% to 30% of patients with lung cancer present with a solitary pulmonary nodule, which may be difficult to differentiate from a benign nodule.²⁴² Certain morphologic and physiologic features, however, may suggest a diagnosis of lung cancer:

1. **Size.** The larger the nodule, the more likely it is to be malignant.^{76, 86, 273} Small size, however, cannot be used to reliably exclude lung cancer, since up to 42% of resected lung cancers are less than 2 cm in diameter.^{203, 242, 269}
2. **Margins.** Lung cancers typically have irregular or spiculated margins.^{76, 202, 225, 269, 273} Although suggestive of lung cancer, these findings can occasionally be seen with benign nodules.^{76, 273} Furthermore, a smooth margin, a feature typical of benign nodules, cannot be used to exclude lung cancer, because 20% of malignant nodules have this appearance.²⁰⁵
3. **Internal morphology.** Except for fat (attenuation, -40

to -120 Hounsfield units [HU]) and calcification within a nodule, internal morphology is unreliable in distinguishing lung cancer from a benign nodule.^{76, 160, 204, 273} Calcification occurs histologically in up to 14% of lung cancers and may be detected by CT.^{123, 159} The calcification is typically amorphous in appearance (Fig. 28-17), unlike the diffuse solid, central punctate, laminated, or popcorn-like calcifications that are diagnostic of benign nodules. Amorphous calcification, however, is not diagnostic of lung cancer, because similar calcifications are occasionally detected in benign lesions. Cavitation occurs in benign nodules and lung cancer. Malignant nodules typically have thick, irregular walls, whereas benign nodules have smooth, thin walls.^{259, 260, 273} These findings, however, are not specific, and wall thickness cannot be used to confidently differentiate benign nodules from lung cancer.

4. **Growth.** Lung cancers typically double in volume (an increase of 26% in diameter) between 30 and 400 days (average, 240 days).¹¹⁹ Although absence of growth over a 2-year period is usually reliable for confirming that a nodule is **benign**,^{72, 73, 118} it is difficult to reliably detect growth in small nodules because the small change in diameter associated with a doubling of volume may not be visible on radiographs. The use of CT can improve the accuracy of growth assessment. It has been reported that growth can be detected in lung cancers as small as 5 mm when CT imaging is repeated within 30 days.²⁶⁴ Furthermore, the measurement of serial volumes of small nodules (which increase proportionally faster than diameters), may be an accurate and potentially useful method for assessing the rate of **growth**.²⁶⁵ At present, the determination of when and how to observe and image small nodules in the assessment of tumor growth rate has not been resolved.
5. **Blood supply.** Blood supply to malignant pulmonary nodules is qualitatively and quantitatively different from the blood supply to benign nodules. Contrast-enhanced CT can be used to image this difference by determining nodule enhancement. Typically, malignant nodules enhance more than 20 HU, whereas benign nodules enhance less than 15 HU (Fig. 28-18).²²³
6. **Metabolism.** Metabolism of glucose is typically increased in lung cancer cells. Positron emission tomography (PET), using a D-glucose analog, ¹⁸F-2-deoxy-D-glucose (FDG), can be used in imaging this increase and in differentiating malignant from benign nodules.¹⁹⁷

Figure 28-17. Non-small-cell lung cancer manifesting as a calcified mass. CT shows a large, right upper lobe mass with mediastinal invasion. Scattered areas of amorphous calcification in the mass are typical of, but not diagnostic for, malignancy.

Figure 28-18. Non-small-cell cancer appearing as an enhancing nodule after administration of contrast material. *A*, Non-contrast-enhanced CT scan shows a left lung nodule with an attenuation value of 24 Hounsfield units (HU). *B*, Contrast-enhanced CT scan shows nodule enhancement of 70 HU and central necrosis. Enhancement of more than 20 HU suggests malignancy. Resection revealed non-small-cell cancer. (Courtesy of Tom Hartman, M.D., Mayo Clinic, Rochester, Minn.)

Nodules as small as 1 cm can be imaged; if FDG uptake is low, the nodules are almost certainly benign.^{41, 101, 114, 173, 174} Nodules with increased FDG uptake are generally considered malignant (Fig. 28-19), although inflammatory and infectious processes (e.g., rheumatoid nodules, tuberculosis, histoplasmosis) may result in increased FDG uptake.^{101, 173, 174, 238}

Staging

Non-Small-Cell Lung Cancer. Because treatment and prognosis depend on the anatomic extent of NSCLC at initial presentation, accurate assessment is important.^{145, 150} The International Staging System for Lung Cancer is used to describe the extent of NSCLC in terms of the primary

tumor (T status), lymph nodes (N status), and metastases (M status) (Table 28-2).¹⁴⁵ The TNM descriptors can be determined clinically (history, physical examination, radiologic imaging) or by pathologic analysis of samples obtained by biopsy or surgery. In general, the clinical stage underestimates the extent of disease when compared with the pathologic stage.¹⁴⁵

Primary Tumor (T Status). The T status defines the size, location, and extent of the primary tumor. Because the extent of the primary tumor determines therapeutic management (surgical resection or palliative radiotherapy or chemotherapy), imaging is often performed to assess the degree of pleural, chest wall, and mediastinal invasion.

CT is useful in confirming gross chest wall invasion

Figure 28-19. Non-small-cell lung cancer seen as hypermetabolic nodule on a PET scan with ¹⁸F-fluorodeoxyglucose (FDG-PET). *A*, CT scan shows a nodule in the right upper lobe. The irregular margin suggests malignancy. *B*, Axial PET image with FDG shows increased uptake within the nodule (arrow) when compared to adjacent mediastinum. Findings suggest malignancy. Resection revealed squamous cell cancer. M, mediastinum; V, vertebral body.

Table 28–2. International Staging System for Lung Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus* (i.e., not in the main bronchus)
T2	Tumor with any of the following features of size or extent: >3 cm in greatest dimension Involves main bronchus, ≥ 2 cm distal to the carina Invades the visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural or pericardial effusion,† or with satellite tumor nodule(s) within the ipsilateral primary-tumor lobe of the lung
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and intrapulmonary nodes involved by direct extension of the primary tumor
N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Distant Metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present‡

*The uncommon superficial tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified T1.

†Most pleural effusions associated with lung cancer are due to tumor. However, there are a few patients in whom multiple cytopathologic examinations of pleural fluid show no tumor. In these cases, the fluid is nonbloody and is not an exudate. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient's disease should be staged T1, T2, or T3. Pericardial effusion is classified according to the same rules.

‡Separate metastatic tumor nodule(s) in the ipsilateral nonprimary-tumor lobe(s) of the lung also are classified M1.

From Mountain CF: Revisions in the international system for staging lung cancer. *Chest* 111:1710–1717, 1997.

(Fig. 28–20) but is inaccurate in differentiating between anatomic contiguity and subtle invasion.^{100, 182, 184, 266} Findings suggestive of chest wall invasion include^{100, 184}:

- Tumor-pleura contact extending over more than 3 cm
- An obtuse angle at the tumor-pleura interface
- Thickening of the pleura or increased attenuation of the extrapleural fat adjacent to the tumor

Although magnetic resonance imaging (MRI) offers su-

Figure 28–20. Non-small-cell lung cancer and chest wall invasion. CT scan shows a left upper lobe lung mass with destruction of the adjacent rib and the vertebral body.

perior soft tissue contrast resolution, the sensitivity (63% to 90%) and specificity (84% to 86%) of MRI in identifying chest wall invasion is similar to that of CT (Fig. 28–21).^{100, 166, 182, 247} MRI is, however, particularly useful in the evaluation of superior sulcus tumors and can be used to assess invasion of the brachial plexus, subclavian vessels, and vertebral bodies (Fig. 28–22).^{100, 247, 248}

Imaging with CT or MR is useful in confirming gross invasion of the mediastinum (Figs. 28–23 and 28–24), but these modalities are inaccurate in determining subtle invasion (56% to 89% and 50% to 93%, respectively).^{100, 126, 134, 148, 247} CT and MRI findings that can be useful in suggesting subtle mediastinal invasion include^{71, 84, 100, 134}:

- Tumor-mediastinal contact extending over more than 3 cm
- Obliteration of the fat plane between the mediastinum and tumor
- Tumor contacting more than 90 degrees of the aortic circumference

Primary lesions associated with malignant pleural effusions or pleural metastases are classified as T4 lesions. Up to 33% of patients with NSCLC have pleural metastases at presentation.^{5, 145} The diagnosis of pleural metastases or malignant effusion, however, can be difficult to confirm. Pleural thickening and nodularity on CT scans suggests metastatic pleural disease (Fig. 28–25), but these abnormalities may not be present in association with a malignant effusion.¹⁸² Furthermore, cytologic evaluation is positive in only approximately 66% of patients with a malignant pleural effusion at presentation.⁵ In the absence of fluid with positive findings in cytologic studies, a T4 classification is still assigned if the effusion appears to be from the underlying malignancy.^{144, 145}

Regional Lymph Nodes (N Status). The presence and location of nodal metastasis are of major importance in determining management and prognosis in patients with NSCLC.¹⁴⁶ To enable a consistent and standardized description of N status, nodal stations are defined by the American Thoracic Society in relation to anatomic structures or

Figure 28-21. Small-cell lung cancer and chest wall invasion. *A*, CT shows a large, well-circumscribed peripheral lung mass with invasion of the chest wall. *B*, Coronal fast spin-echo MRI shows mass abutting the chest wall and the surrounding ribs (asterisks) and extending through the intercostal space into the soft tissues of the chest wall (arrow).

Figure 28-22. Pancoast's tumor with local chest wall invasion. *A* and *B*, Coronal T1-weighted MR images show a mass (M) in the apex of the left hemithorax, with loss of the adjacent soft tissue plane consistent with local invasion (arrowheads). Asterisks in *A* indicate rib.

Figure 28-23. Non-small-cell cancer with mediastinal invasion. CT scan shows a large, left upper lobe mass with invasion of the anterior mediastinum. Broad abutment and loss of soft tissue plane between the mass and the transverse aorta suggest vascular invasion.

Figure 28-24. Non-small-cell lung cancer invading the left atrium. Axial T1-weighted MR image shows a left lower lobe mass that has an intermediate signal intensity extending into the left atrium (*arrows*). A, aorta; LA, left atrium. (From Erasmus JJ, McAdams HP, Donnelly LF, Spritzer CE: MR imaging of mediastinal masses. *MRI Clin North Am* 8: 59-89, 2000.)

Figure 28-25. Non-small-cell lung cancer and pleural metastases. Contrast-enhanced CT shows a large right pleural effusion and enhancing nodular pleural metastases (*arrowheads*). Arrow indicates compressive atelectasis of the right lower lobe and a metastatic left rib lesion.

Figure 28-26. Nodal stations defined in relation to anatomic structures or boundaries. Superior mediastinal nodes: 1, highest mediastinal; 2, upper paratracheal; 3, prevascular and retrotracheal; 4, lower paratracheal (including azygos nodes); Aortic nodes: 5, subaortic (anteroposterior window); 6, para-aortic (ascending aorta or phrenic). Inferior mediastinal nodes: 7, subcarinal; 8, paraesophageal (below carina); 9, pulmonary ligament. N₁ nodes: 10, hilar; 11, interlobar; 12, lobar; 13, segmental; 14, subsegmental. (From Mountain CF: Revisions in the international system for staging lung cancer. *Chest* 111:1710-1717, 1997.)

boundaries that can be identified before and during thoracotomy (Fig. 28-26 and Table 28-3).^{145, 146}

Size is the only criterion used to diagnose nodal metastases, with nodes greater than 10 mm in short-axis diameter considered abnormal.^{69, 70} Because enlarged nodes can be hyperplastic or reactive and small nodes can harbor metastases, the accuracies of CT and MRI in detecting ipsilateral metastases to hilar nodes (N1 disease) are only 62% to 88% and 68% to 74%, respectively.^{68, 126, 135, 200, 246} Fortunately, accuracy in determining N1 disease is usually not essential, because in most cases this does not prevent surgical resection.^{135, 182} The accuracies of CT (56% to 82%) and MRI (50% to 82%) in detecting mediastinal nodal metastases (N2, N3 disease) are also not optimal.^{7, 100, 126, 148, 211, 246, 247}

FDG-PET is more accurate (range, 81% to 96%) than CT and MRI in determining N status.^{44, 175, 213, 244} FDG-PET is particularly useful in detecting metastatic disease in normal-sized nodes and in differentiating hyperplastic nodes from enlarged nodal metastases (Fig. 28-27).^{213, 241, 244} It has been advocated that a normal FDG-PET scan and normal-sized nodes on CT can obviate the need for mediastinoscopy in some patients with potentially resectable lung cancer.^{213, 241, 244}

Metastatic Disease (M status). Patients with NSCLC commonly have extrathoracic metastases to the adrenal glands, liver, brain, bones, and lymph nodes at presentation.^{100, 145, 181} The role of imaging in detecting these metastases, however, is not clearly defined. Because a normal

clinical examination result, combined with normal routine laboratory tests, such as hematocrit, alkaline phosphatase, gamma-glutamyl transferase (GGT), and serum glutamic-oxaloacetic transaminase (SGOT), has a negative predictive value greater than 95%, radiologic evaluation for occult metastases may not be required.^{206, 224} In fact, considering the high cost and low incidence (0.5% to 0.9%) of detecting metastases in patients with T1 N0 to T2 N0 disease and no clinical findings of metastases, it has been suggested that extrathoracic imaging should not be performed in the staging evaluation of these patients.²²⁴ Routine imaging of the abdomen is still performed by many clinicians, however, because of the poor reliability of clinical and laboratory findings in the detection of intra-abdominal metastases.

Metastases to the adrenal glands are common and are detected in up to 20% of patients at presentation (Fig. 28-28).^{100, 155, 164, 167, 168} A small (<3 cm) adrenal mass, however, is more likely to be benign in the absence of other extrathoracic metastases.¹⁰⁰ CT and MRI can be useful in the evaluation of adrenal masses.

CT and MRI features favoring malignancy include^{43, 136, 140,}

- Size greater than 3 cm
- Poorly defined margins
- Irregularly enhancing rim
- Invasion of adjacent structures
- High signal intensity on T2-weighted sequences

A confident diagnosis of benignity can be made if an

Table 28–3. Classification of Regional Lymph Nodes in Lung Cancer

Nodal Station	Anatomic Landmarks
N2 nodes—All N2 nodes lie within the mediastinal pleural envelope:	
1 Highest mediastinal nodes	Nodes lying above a horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline
2 Upper paratracheal nodes	Nodes lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of No. 1 nodes
3 Prevascular and retrotracheal nodes	Prevascular and retrotracheal nodes may be designated 3A and 3P; midline nodes are considered to be ipsilateral
4 Lower paratracheal nodes	The lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope; the lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the mediastinal pleural envelope Researchers may wish to designate the lower paratracheal nodes as No. 4s (superior) and No. 4i (inferior) subsets for study purposes; the No. 4s nodes may be defined by a horizontal line extending across the trachea and drawn tangential to the cephalic border of the azygos vein; the No. 4i nodes may be defined by the lower boundary of No. 4s and the lower boundary of No. 4, as described above
5 Subaortic (aortopulmonary window)	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope
6 Para-aortic nodes (ascending aorta or phrenic)	Nodes lying anterior and lateral to the ascending aorta and the aortic arch or the innominate artery, beneath a line tangential to the upper margin of the aortic arch
7 Subcarinal nodes	Nodes lying caudal to the carina of the trachea, but not associated with the lower lobe bronchi or arteries within the lung
8 Paraeosophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes
9 Pulmonary ligament nodes	Nodes lying within the pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein
N1 nodes—All N1 nodes lie distal to the mediastinal pleural reflection and within the visceral pleura	
10 Hilar nodes	The proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiographically, the hilar shadow may be created by enlargement of both hilar and interlobar nodes
11 Interlobar nodes	Nodes lying between the lobar bronchi
12 Lobar nodes	Nodes adjacent to the distal lobar bronchi
13 Segmental nodes	Nodes adjacent to the segmental bronchi
14 Subsegmental nodes	Nodes around the subsegmental bronchi

From Mountain CF, Dresler CM: Regional lymph node classification for lung cancer staging. *Chest* 111:1718–1723, 1997.

Figure 28–27. Non-small-cell lung cancer and intrathoracic nodal metastasis. A, CT shows an 11-mm right paratracheal node (arrow) and smaller, normal-sized aortopulmonary window lymph nodes (arrowheads). B, Axial PET image with ^{18}F -fluorodeoxyglucose (FDG-PET) shows markedly increased uptake in mediastinal nodes. Mediastinoscopy confirmed metastatic disease (arrows). T, trachea; V, vertebral body.

Figure 28-28. Non-small-cell lung cancer and adrenal metastasis. *A*, CT shows a nodule in the left lower lobe. There is no hilar or mediastinal adenopathy. *B*, CT of the abdomen reveals a left adrenal mass (arrow). Biopsy confirmed metastasis.

adrenal mass has an attenuation value less than 10 HU on a non-contrast-enhanced CT scan.¹⁴ MRI, using chemical shift analysis and dynamic gadolinium enhancement, can also be used to determine whether an adrenal mass is benign (Fig. 28-29).^{13, 165, 198} Unfortunately, the status of some adrenal lesions remains indeterminate after radiologic evaluation, and biopsy is required.¹⁷⁸

CNS metastases are common and are detected in up to 18% of patients at presentation (Fig. 28-30).^{89, 139} Up to 10% of these patients (usually with large-cell carcinomas and adenocarcinomas) are asymptomatic.^{89, 139, 154, 195} Consequently, it has been suggested that routine CT of the brain should be performed in the initial staging evaluation of all patients with NSCLC.⁵⁶ Because CNS metastases are usually associated with neurologic signs and symptoms, however, imaging for CNS metastases in asymptomatic patients with NSCLC is not considered cost-effective and is not generally recommended.^{30, 206}

Patients with skeletal metastases are usually symptomatic or have laboratory abnormalities indicating bone metastases.¹⁹⁵ Because occult skeletal metastases are only occasionally detected in asymptomatic patients by imaging, it is recommended that bone radiographs, technetium 99m-methylene diphosphonate (^{99m}Tc-MDP) bone scintigraphy, and MRI be performed only to evaluate a history of focal bone pain or elevated alkaline phosphatase.^{122, 137, 195, 206, 214}

Because staging performed on the basis of symptomatology, abnormal laboratory indices, and conventional radiologic imaging incorrectly assigns some patients with NSCLC, FDG-PET is being used as an additional imaging modality to improve staging accuracy. FDG-PET has a higher sensitivity and specificity than CT in detecting metastases to the adrenals, bones, and extrathoracic lymph nodes.^{20, 52, 114, 129, 195, 238, 249} Whole body PET imaging allows the physician to stage intrathoracic and extrathoracic disease in a single study, to detect occult extrathoracic metas-

Figure 28-29. Non-small-cell lung cancer and incidental adrenal adenoma evaluated by chemical shift MRI. *A*, In-phase (TR = 200 msec, TE = 4.2 msec) spoiled gradient-recalled echo MR image shows a left adrenal mass (arrow) that is slightly hyperintense compared with the spleen (S). *B*, Opposed-phase (TR = 200 msec, TE = 1.8 msec) spoiled gradient-recalled echo MR image shows that the left adrenal mass is now markedly hypointense. The findings are typical of those for adenoma. The patient underwent resection of primary lung malignancy.

Figure 28–30. Non–small-cell lung cancer and brain metastases at presentation manifesting as ataxia. *A*, CT shows a spiculated right upper lobe nodule. *B*, Axial contrast-enhanced cranial CT scan shows enhancing metastases in the temporal lobe and the cerebellum (arrows).

tases in 11% to 14% of patients selected for curative resection, and to alter management in up to 40% of cases (Fig. 28–31).^{114, 238, 249}

Staging Classification. The International Staging System for Lung Cancer combines the TNM subsets into categories, or stages, that have similar treatment options and prognosis (Table 28–4).^{17, 145}

Stages I and II. Patients with *stage I* disease are typically optimal candidates for surgical resection with survival rates of 57% to 85%.¹⁴⁵ The prognostic implications of larger tumor size and location and the involvement of intrapulmonary and hilar lymph nodes are reflected in the decreased 5-year survival rates of 34% and 22% to 24% in patients with *stage IIA* (T1 N1 M0) and *stage IIB* (T2 N1 M0, T3 N0 M0) disease, respectively.¹⁴⁵

Table 28–4. Stage Grouping: Tumor-Node-Metastases (TNM) Subsets

Stage	TNM Subset		
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T1–2	N1	M0
IIB	T3	N0	M0
IIIA	T1–2	N2	M0
	T3	N1–2	M0
IIIB	T4	N0–2	M0
	T1–4	N3	M0
IV	Any T	Any N	M1

Stage III. *Stage IIIA* (T3 N1 M0, T1–T3 N2 M0) identifies patients with locally advanced disease (extrapulmonary extension of the primary tumor) and ipsilateral hilar or mediastinal nodes. These patients are potential surgical candidates, although extracapsular extension of metastasis or involvement of high paratracheal nodes is a contraindication to curative resection.¹⁴⁴ Increasing tumor size and extent of local invasion appear to be directly related to the extent of lymph node involvement and the decrease in survival rates.¹⁴⁵ The 5-year survival rate is 9% to 13% in clinically staged patients and 23% to 25% in surgical-pathologic staged patients.¹⁴⁵

Stage IIIB (T4 N0–2 M0, T1–T4 N3 M0) identifies patients with nonresectable NSCLC (i.e., satellite nodules in the lobe with the primary tumor, malignant effusion, invasion of nonresectable structures, contralateral hila, or mediastinal nodal disease).¹⁴⁵ Most stage IIIB patients receive radiation therapy and adjuvant chemotherapy, and the 5-year survival is 3% to 8%.¹⁴⁵ The classification of satellite nodules as T4 disease, however, may imply a worse prognosis than is warranted. It has been advocated that these patients undergo definitive resection if there are no other contraindications to surgery (Fig. 28–32).^{19, 112}

Stage IV. Stage IV patients have distant metastatic disease, including metastatic nodules in the ipsilateral nonprimary tumor lobes.¹⁴⁵ With the uncommon exception of a resectable intrathoracic NSCLC and a resectable solitary brain metastasis, stage IV carries the worst prognosis, with only 1% of patients alive at 5 years.^{145, 194}

Small-Cell Lung Cancer. SCLC is generally staged according to the Veteran's Administration Lung Cancer

Figure 28-31. Non-small-cell lung cancer and extrathoracic metastases. *A*, Posteroanterior chest radiograph shows a right upper lobe mass. A small, right pleural effusion can be seen. *B*, CT reveals a small, right adrenal mass (*arrow*) and confirms a small right pleural effusion. *C*, Whole body PET image with ^{18}F -fluorodeoxyglucose (FDG-PET) shows increased uptake in the primary lung mass (*small arrow*) and in the adrenal metastasis (*arrowhead*). Focal areas of increased uptake in the upper aspect of the left hemithorax and pelvis (*large arrows*) were unsuspected bone metastases. B, bladder activity; C, cardiac activity.

Figure 28-32. Non-small-cell lung cancer appearing as two lung nodules. *A* and *B*, CT scan shows two nodules in the left lower lobe, one of which is cavitary (*arrow* in *A* and in *B*). A satellite nodule in the ipsilateral lobe is classified as T4, not M1, disease.

Figure 28-33. Small-cell lung cancer with disseminated metastases at presentation. **A**, Posteroanterior chest radiograph shows a poorly margined mass in the right upper lobe (*arrowheads*) and a smaller right upper lobe nodule (*arrow*). **B**, CT shows large, bilateral necrotic adrenal metastases. **C**, Axial contrast-enhanced cranial MR image shows enhancing cerebellar metastases.

Study Group (VALG) recommendations as *limited disease* (LD) or *extensive disease* (ED).³⁷ LD defines tumor confined to a hemithorax and the regional lymph nodes. Unlike the TNM classification for NSCLC, metastases to the ipsilateral supraclavicular, contralateral supraclavicular, and mediastinal lymph nodes are considered local disease. Additionally, an ipsilateral malignant pleural effusion is often treated as limited disease.³⁷ ED includes tumor with non-contiguous metastases to the contralateral lung and distant metastases.^{37, 215}

Most patients with SCLC have ED at presentation (Fig. 28-33).^{92, 100} Common sites of metastatic disease include the liver, bone, bone marrow, brain, and retroperitoneal lymph nodes.⁹² Although there is no consensus regarding the imaging and invasive procedures that should be performed in the staging evaluation of patients with SCLC, MRI has been advocated to assess the liver, adrenals, brain, and axial skeleton in a single study.⁹² Evaluation of extrathoracic metastatic disease usually includes the following:

1. **Bone marrow aspiration, ^{99m}Tc-MDP bone scintigraphy, and MRI.** Patients with bone (30%) and bone marrow (17% to 34%) metastases are often asymptomatic, and blood alkaline phosphatase levels are frequently normal.^{1, 37, 209, 210} Because isolated bone and bone marrow metastases are uncommon, however, routine bone mar-

row aspiration and radiologic imaging for occult metastases are usually performed only if there are other findings of ED.

2. **Brain MRI.** CNS metastases are common (10% to 27%) at presentation, and approximately 5% of patients are asymptomatic.^{1, 18, 37} Because therapeutic CNS radiation and chemotherapy can decrease morbidity and improve prognosis, routine MRI of the brain is recommended in patients with SCLC.^{37, 46, 240}
3. **CT or MRI of the abdomen.** Metastases to the liver (30%) and retroperitoneal nodes (11%) are common at presentation.^{1, 37} Because patients are often asymptomatic and liver function tests can be normal, staging evaluation routinely includes CT or MRI of the abdomen.

Carcinomas with Pleomorphic Sarcomatoid or Sarcomatous Elements

Sarcomatoid carcinomas are lung malignancies containing carcinomatous and sarcomatous components.^{149, 254} They represent a clinicopathologic continuum that includes pulmonary blastoma, carcinosarcoma, and carcinomas with spindle or giant cells.^{149, 254}

Carcinomas with Spindle or Giant Cells

Sarcomatoid carcinomas (pleomorphic carcinoma, spindle cell carcinoma, giant cell carcinoma, carcinosarcoma) are rare, composing 0.3% to 1% of malignant lung neoplasms.^{48, 149} Most patients are men, and mean age at presentation is 65 years (range, 44 to 78 years).^{90, 149} Most patients present with cough, dyspnea, hemoptysis, chest pain, or weight loss.^{48, 90, 149} Although sarcomatoid carcinomas are usually localized at presentation, distant metastases occur frequently and the prognosis is poor.^{90, 149, 254}

Radiologically, these neoplasms can manifest either as large peripheral masses or as polypoid endobronchial lesions with atelectasis or postobstructive pneumonia.^{90, 98, 149, 254} Calcification and cavitation are uncommon, but necrosis and hemorrhage can manifest as heterogeneous attenuation on CT.^{98, 149, 254} Hilar or mediastinal adenopathy is uncommon.¹⁴⁹ Pleural effusion can occur as a result of local invasion.⁹⁸ Metastases involve sites similar to those of lung cancer (lung, liver, bones, adrenals, brain).²⁵⁴

Pulmonary Blastoma

Pulmonary blastoma is a rare malignancy that makes up an estimated 0.25% to 0.5% of primary lung tumors.^{62, 104, 106, 111} The tumor derives its name from its histologic resemblance to fetal lung tissue. Pulmonary blastomas, however, are thought to arise from primitive pluripotential stem cells and may represent a variant of carcinosarcoma.²⁵⁵ Although the age range at presentation is wide (0 to 80 years), these tumors typically occur in adults, with a peak incidence between 40 and 60 years of age.^{62, 104, 106, 111} Patients are often symptomatic at presentation; cough, hemoptysis, and chest pain are frequent manifestations.¹⁰⁴ Pulmonary blastoma is an aggressive malignancy and the overall 5-year survival rate is poor.^{34, 62}

Radiologically, pulmonary blastomas typically manifest as large (range, 2.5 to 26 cm), well-margined masses located peripherally in the lung (Fig. 28–34).^{62, 250} Multiple masses, cavitation, and calcification are rare.²⁵⁰ Local invasion of the mediastinum and pleura occurs in 8% and 25%

of cases, respectively.⁶² Metastases to hilar and mediastinal lymph nodes are present in 30% of resected cases.⁶² Extrathoracic metastases are common and have a distribution similar to that of lung cancer.^{62, 111}

Carcinoid Tumor

Primary pulmonary carcinoid tumors are low-grade malignancies that constitute 1% to 2% of primary lung tumors.¹³³ They are classified histologically as typical (80% to 90%) or atypical (10% to 20%) tumors, depending on the degree of cellular atypia.^{38, 96, 219}

Typical carcinoid tumors occur with equal frequency in men and women; the mean age at diagnosis is 35 to 50 years.^{38, 219} Tumors usually arise in lobar, segmental, or proximal subsegmental bronchi (80% to 85%) and are generally 1 to 4 cm in size. They rarely metastasize to regional nodes or beyond the thorax.³⁸

Atypical carcinoid tumors are usually discovered at a slightly older age (mean, 55 to 60 years), are often larger, and have equal central and peripheral distributions.^{96, 219} They behave more aggressively than do typical carcinoid tumors and frequently metastasize to regional nodes, lung, liver, and bone.^{29, 96}

Clinical manifestations depend on the histologic type and the location of the carcinoid tumor.²¹⁹ Peripheral tumors are usually asymptomatic, whereas central neoplasms can manifest as cough, hemoptysis, or recurrent infection (Fig. 28–35).³⁸ Paraneoplastic manifestations, such as carcinoid syndrome (cutaneous flushing, bronchospasm, chronic diarrhea, and valvular heart disease) and Cushing's syndrome, are rare and more common with atypical carcinoid tumors.^{38, 133}

Radiologically, carcinoid tumors manifest most commonly as central endobronchial masses, with or without atelectasis or consolidation (Fig. 28–36).²⁷² A peripheral, well-margined pulmonary nodule is a less common manifestation (Fig. 28–37). The tumors are usually less than 3 cm in size, although occasionally they may be as large as

Figure 28–34. Pulmonary blastoma seen as a lobular pulmonary mass. *A*, Posteroanterior chest radiograph shows a sharply margined, lobular mass in the right upper lobe. *B*, CT confirms the lung mass and shows heterogeneous attenuation consistent with necrosis.

Figure 28-35. Typical carcinoid tumor manifesting as recurrent pulmonary infections. *A* and *B*, CT shows a mass in the segmental bronchus of the left lower lobe (arrows in *A*), left lower lobe volume loss, and distal bronchiectasis in the atelectatic lung (arrowheads in *B*).

10 cm in diameter.^{133, 147, 239} Calcification is detected by CT in approximately 25% of carcinoid tumors (Fig. 28-38).²⁷² Hilar and mediastinal adenopathy and extrathoracic metastases are uncommon at presentation and occur more frequently in patients with atypical carcinoid tumors.^{127, 147, 153}

Carcinomas of the Salivary Gland Type **Mucoepidermoid Carcinoma**

Mucoepidermoid carcinoma (formerly categorized as a bronchial adenoma) is a rare tracheobronchial tumor composed of distinct areas of epidermoid cells and mucus-secreting cells. Although patients vary widely in age at presentation, the tumors are more common in adults, with

a peak incidence between 35 and 45 years.²⁶⁷ They typically occur in the main or lobar bronchi but, in rare instances, may be located in the trachea and periphery of the lung.^{229, 232, 267} They are usually slow-growing, low-grade neoplasms with a benign clinical course. Although occasionally they exhibit aggressive local behavior, metastases are uncommon.^{82, 267}

Radiologically, the tumor usually manifests as a central endobronchial mass and less commonly as a polypoid intraluminal tracheal or peripheral lung nodule or a mass.

Adenoid Cystic Carcinoma (Cylindroma)

Adenoid cystic carcinoma (formerly categorized as a bronchial adenoma) is an uncommon primary tumor of the lung. It occurs most often in the trachea (Fig. 28-39) and

Figure 28-36. Typical carcinoid appearing as a central endobronchial lesion. *A*, Posteroanterior chest radiograph shows complete atelectasis of right lower lobe (arrowheads) with compensatory hyperinflation of the left lung. Note the displacement of the anterior junction line (arrows). *B*, CT confirms atelectasis of the right lower lobe and reveals an endobronchial mass (M) with marked narrowing of the bronchus intermedius (arrow).

Figure 28-37. Typical carcinoid seen as a solitary peripheral nodule. CT shows a well-circumscribed small nodule in the right upper lobe.

main bronchi, although 10% to 15% are located peripherally in the lung.^{3, 31, 36, 66} Adenoid cystic carcinomas occur with equal frequency in men and women; the mean age at diagnosis is 45 to 51 years.^{130, 142} They typically exhibit slow, progressive growth.³¹ Metastases to regional lymph nodes, lung, bone, liver, and brain are common but tend to occur late in the disease.⁶⁶

Radiologically, the tumor usually manifests as an endotracheal or endobronchial mass that is typically lobulated or polypoid and encroaches on the airway lumen. Masses can be circumferential and may manifest as diffuse stenosis.¹³² A less common manifestation is a peripheral lung nodule or mass.^{31, 66}

Mesenchymal Tumors

Primary Pulmonary Sarcomas

Primary lung sarcomas with a vascular origin (angiosarcomas, epithelioid hemangioendotheliomas) are rare primary tumors of lung.^{222, 256} Most angiosarcomas are lung

metastases, and the existence of primary pulmonary angiosarcoma has been questioned.²⁰⁸ The tumor usually occurs in young adults, and the most frequent radiologic finding is multiple, bilateral nodules.²²²

Epithelioid hemangioendothelioma is typically seen in women younger than 40 years of age (range, 7 to 76 years).^{24, 187, 190, 256} Most patients are asymptomatic at presentation; complaints include weight loss, dyspnea, chest pain, cough, and hemoptysis.^{24, 35, 256} Behavior is typically indolent, with survival reported up to 24 years following resection.³⁵

Pulmonary epithelioid hemangioendothelioma usually manifests radiologically as multiple, 1- to 2-cm pulmonary nodules (Fig. 28-40).^{35, 190, 256} Calcification is rarely detected but is common histologically.^{35, 190} Hilar adenopathy and pleural effusions occur in 9% of patients.¹⁹⁰ Multiorgan involvement, most commonly the liver, occurs occasionally and may represent metastatic disease or multicentric origin of the tumor.^{15, 45, 47, 191}

Primary lung sarcomas with a spindle origin are rare, accounting for fewer than 0.5% of primary lung malignan-

Figure 28-38. Atypical carcinoid tumor with rib and hepatic metastases at presentation. CT shows a large endobronchial mass with dense punctate calcification.

Figure 28-39. Adenoid cystic carcinoma manifesting as a tracheal mass. CT shows a soft tissue mass (arrowheads) arising from the lateral wall of the trachea (T). A polypoid endoluminal component can be seen.

Figure 28-40. Epithelioid hemangioendothelioma appearing as multiple pulmonary nodules. **A**, Posteroanterior chest radiograph shows numerous small bilateral pulmonary nodules. Note the absence of hilar and mediastinal adenopathy. **B**, CT confirms the numerous small, bilateral, well-circumscribed nodules. **C**, CT scan of the abdomen reveals small, bilateral, low-attenuation hepatic epithelioid hemangioendotheliomas.

cies.^{8,222} Spindle cell sarcomas (malignant fibrous histiocytoma, hemangiopericytoma, fibrosarcoma, leiomyosarcoma, synovial sarcoma) are the most common primary pulmonary sarcomas.^{94, 141, 222, 270} They are a heterogeneous group of tumors with morphologic similarities to their extrathoracic counterparts.⁸ The diagnosis is established only after metastatic disease and sarcoma-like primary lung malignancies (sarcomatoid carcinomas) have been excluded.^{8, 62, 90, 149} Pulmonary sarcomas have a peak incidence in the fifth and sixth decades.^{91, 141, 222, 268, 270} The tumors are usually slowly growing with late metastases, and the prognosis is generally better than that with lung cancer.²²²

Radiologically, pulmonary sarcomas are more com-

monly located peripherally, although central and endobronchial masses are reported.^{8, 91, 141, 222, 268} Lesions range in size from 0.6 to 25 cm; they are typically sharply marginated and occasionally calcified (Figs. 28–41 and 28–42).^{8, 78, 94, 141, 222} Cavitation is uncommon, although CT can show heterogeneous attenuation resulting from necrosis within the mass.^{78, 94} Diagnostic angiographic features have been reported for hemangiopericytomas in the soft tissues and bone.^{78, 263} The pathognomonic hypervascularity that occurs as a result of the numerous vascular spaces within the tumor, however, are seldom seen on CT scans or MR images of primary pulmonary hemangiopericytomas (Fig. 28–43).

Figure 28–41. Synovial carcinoma of left lung seen as a large mass. *A*, CT shows a large mass in the left lower lobe with a small focal calcification (*arrow*). A small pleural effusion can be seen. *B* and *C*, Coronal T1-weighted (*B*) and fast spin-echo (*C*) MR images show a large heterogeneous mass abutting the diaphragm without signs of invasion. A small pleural effusion (*P*) can be seen. *L*, liver; *M*, mass.

Figure 28-42. Malignant fibrous histiocytoma manifesting as a solitary pulmonary nodule. CT shows a left upper lobe nodule with irregular margins.

Lymphoproliferative Disorders

Primary Lymphomas

Primary pulmonary lymphomas account for fewer than 1% of all lymphomas.^{32, 57, 103, 226} The diagnosis is generally considered if (1) the lymphoid proliferation is monoclonal and (2) there are no sites of extrathoracic lymphoma at presentation or for at least 3 months after diagnosis.^{16, 32, 57, 183, 226} Criteria used to define primary pulmonary lymphomas are variable, however; some authors restrict the diagnosis to pulmonary parenchymal disease only, but others include hilar adenopathy with or without mediastinal adenopathy.

Primary pulmonary lymphomas encompass a histologic spectrum of malignant lymphomas including non-Hodgkin's lymphoma, Hodgkin's lymphoma, and lymphoproliferative disorders associated with immunodeficiency states (e.g., post-transplant lymphoproliferative disorders, acquired immunodeficiency syndrome).⁷⁷ Most primary extranodal lymphomas arise from mucosa-associated lymphoid tissue (MALT) and are sometimes referred to as *malto-mas*.^{32, 55, 77, 80, 103} In the lung, primary lymphomas are thought to arise from bronchus-associated lymphoid tissue (BALT) that occurs in the airway as a response to chronic stimulation.²³¹ These tumors are typically non-Hodgkin's lymphomas of B-cell immunophenotype composed of monoclonal lymphocytic cells with low histologic grade, and they have now been classified as extranodal marginal zone lymphomas.^{57, 80, 103, 115}

Primary pulmonary lymphomas tend to remain localized

Figure 28-43. Hemangiopericytoma appearing as a large, hypervascular mass. A, Contrast-enhanced CT shows a large, right lower lobe mass. Large vessels can be seen within the mass. B and C, Axial T1-weighted (B) and fast spin-echo (C) MR images show a heterogeneous mass in the right hemithorax. Flow voids can be seen within the intratumoral vessels.

Figure 28-44. Primary pulmonary lymphoma seen as chronic consolidation. *A*, Posteroanterior chest radiograph shows a poorly margined opacity in the left lung. Note the absence of hilar and mediastinal adenopathy. *B*, CT shows a homogeneous opacity containing air-bronchograms in the left upper lobe.

to the lung, although recurrence after treatment, often at extrapulmonary sites, occurs in up to 50%.^{32, 57, 103, 115} High-grade non-Hodgkin's lymphomas, which constitute approximately 13% of primary pulmonary lymphomas, are usually B-cell tumors with aggressive behavior and a poor 5-year survival rate.^{32, 57, 103, 115}

Most patients are 55 to 60 years old, although the age range is wide.^{97, 115} Patients with low-grade lymphomas are usually asymptomatic at presentation, whereas patients with high-grade tumors usually present with cough, fever, or weight loss.³²

The most common radiologic manifestations are a solitary nodule or mass and focal consolidation (Fig. 28-44).^{32, 57, 109, 115, 158} Less common manifestations include multiple nodules or masses, multifocal consolidation, reticulonodular opacities, and atelectasis (Fig. 28-45).^{32, 57, 115, 158} Hilar adenopathy is rare, and pleural effusions occur in 7% to 25% of patients.^{32, 97, 103}

Benign Neoplasms of the Lung

Hamartoma

Hamartomas constitute 0.25% of all primary lung tumors and, although uncommon, are the most common benign tumor of lung.¹⁹³ The term *hamartoma* was initially used to describe lesions with an abnormal composition or disorganized arrangement of normal lung tissue. Now, however, hamartomas are considered true neoplasms containing a mixture of epithelial and mesenchymal tissues.²⁰⁴

Pulmonary hamartomas typically occur in patients older than 30 years, with a peak incidence in the sixth decade (range, 0 to 76 years).^{79, 163, 180, 193} Most patients are asymptomatic; symptoms are typically present with central endobronchial lesions and include hemoptysis, recurrent pneumonia, and dyspnea.^{63, 67, 193}

Hamartomas are typically solitary, well-margined, slightly lobular nodules or masses that are less than 4 cm

Figure 28-45. Primary pulmonary lymphoma manifesting as bilateral pulmonary opacities. *A* and *B*, CT shows focal, poorly margined nodular opacities in both lungs. Air-bronchograms within opacities are suggestive of the diagnosis.

Figure 28-46. Hamartoma appearing as a solitary pulmonary nodule. CT shows a left upper lobe nodule (arrow) anterior to the left pulmonary artery. The diagnosis is suggested by small areas of fat (attenuation, -41 Hounsfield units) within the nodule.

in size (range, 1 to 30 cm).^{63, 67, 180, 193} Most are located peripherally within the lung. Endobronchial hamartomas are less common (up to 20% of cases).^{63, 79, 193} Calcification has been reported in up to 50% but is probably present in fewer than 5% of hamartomas.^{107, 204} The presence of “popcorn” calcification, however, is almost pathognomonic of hamartomas. Fat (CT attenuation, -40 to -120 HU) occurs in up to 50% of cases and is a diagnostic feature (Fig. 28-46).²⁰⁴ Rare radiographic manifestations include cavitation and multiple pulmonary hamartomas.⁹⁹

Granular Cell Tumor

Granular cell tumors (formerly, *granular cell myeloblastomas*) are rare pulmonary neoplasms that are thought to arise from Schwann cells.^{39, 131} Patients are usually adults (peak incidence, 30 to 50 years of age; range, 0 to 59 years), and there is a higher incidence in African Americans.^{39, 102, 169, 170, 186}

Most pulmonary granular cell tumors manifest as small, central endobronchial masses (range, 0.3 to 6.5 cm in diameter).^{39, 85} Multiple lesions, typically in the larger bronchi, are found in up to 25% of cases.^{39, 85} Common radiologic findings include atelectasis and obstructive pneumonia, although slow-growing, solitary pulmonary nodules or masses occur in 12% of cases.^{39, 85}

Sclerosing Hemangioma

Primary pulmonary sclerosing hemangioma is a benign tumor consisting of thin-walled vessels and connective tissue.^{117, 156} Originally thought to represent a vascular tu-

mor, it is now considered to arise from alveolar or bronchiolar epithelium.⁸¹ Most patients are asymptomatic women between 30 and 50 years of age (range, 15 to 77 years).^{95, 221}

Radiologically, pulmonary hemangiomas usually manifest as peripheral, well-marginated solitary pulmonary nodules or masses 0.4 to 8.0 cm in diameter (average, 3.0 cm). Multiple pulmonary nodules and calcification are rare.^{95, 110}

Clear Cell Tumor

Clear cell tumor is a rare neoplasm of the lung.^{65, 116} Most patients are asymptomatic and between 50 and 60 years of age (range, 8 to 70 years).^{64, 65} Almost all the tumors behave in a benign nature, although extrathoracic metastases have been reported.¹⁹² Clear cell tumors typically manifest radiologically as well-marginated solitary pulmonary nodules usually less than 3 cm in diameter (range, 0.7 to 6.5 cm).^{6, 64, 65, 192, 271}

Mediastinum

H. Page McAdams, Jeremy J. Erasmus,
Robert D. Tarver, Charles E. Spritzer

Many excellent textbooks and articles have been written about the mediastinum.^{61, 65, 71, 101, 103, 181} This chapter refers to these articles and reviews the recent literature in regard to the anatomy, pathology, and radiologic manifestations of mediastinal diseases.

Imaging the Mediastinum

Although the chest radiograph is usually the initial study that detects a mediastinal abnormality, computed tomography (CT) is primarily used to assess the location and extent of mediastinal disease; because of its superior contrast resolution, it is also used to characterize the tissue components of masses (Fig. 29-1). CT is also useful for distinguishing vascular variants or benign processes of the mediastinum, such as lipomatosis, from true pathologic conditions.

Although CT is usually used to further evaluate an abnormality detected on the chest radiograph, it may be performed in certain clinical situations when the chest radiograph is normal. For example, because of the strong association between myasthenia gravis and thymoma, CT is often performed in patients with myasthenia gravis even when chest radiographic findings are normal (Fig. 29-2). Also, certain malignancies, such as lung cancer, have a marked predilection for metastasis to mediastinal lymph nodes. These lymph node metastases may not be visible on chest radiographs; consequently, CT is used by most thoracic surgeons and oncologists to assess the mediastinal nodes in patients with lung cancer.

Recent advances in CT imaging (i.e., spiral CT and multidetector-row spiral CT) have further improved the ability of CT to image the mediastinum. By significantly shortening scan time, respiratory motion artifacts are limited and, in some instances, the total dose of iodinated contrast medium can be reduced. Spiral CT data sets can also be effectively reconstructed in a variety of nonaxial planes, often facilitating interpretation of mediastinal abnormalities. The application of nonaxial two-dimensional (2D) and three-dimensional (3D) reconstruction techniques has proved most useful for imaging abnormalities of the central airways and great vessels (Figs. 29-3 and 29-4). For example, in the evaluation of stenoses in obliquely oriented bronchi, these reconstruction techniques can improve diagnostic accuracy and confidence of interpretation, although axial CT images usually provide all the information required for diagnosis. Nevertheless, 2D and 3D images, by presenting anatomic information in a context more familiar to referring clinicians, may demonstrate the loca-

tion and extent of an abnormality in a way that radiologic reports and axial CT images often do not.

Although CT imaging usually provides the requisite information in most patients with mediastinal abnormalities, magnetic resonance imaging (MRI), because of its multiplanar capability and high contrast resolution, is occasionally used to further evaluate the location and extent of disease. MRI is the modality of choice for imaging neurogenic tumors because not only does it demonstrate the number and nature of the lesions but also it optimally depicts intraspinal extension.

Additionally, MRI is useful (1) in confirming the cystic nature of mediastinal lesions that appear solid on CT (Fig. 29-5) and (2) in demonstrating vascular structures in patients in whom iodinated intravenous (IV) contrast medium is contraindicated (Fig. 29-6). Compared with CT, MRI has two potential disadvantages for imaging mediastinal abnormalities: its ability to demonstrate calcification and its spatial resolution are relatively poor.

CT Scanning Techniques

Techniques for CT scanning of the chest vary from institution to institution. Although standard protocols are frequently used without modification, they are occasionally altered to address specific clinical concerns.

Patient Considerations

Most patients are scanned in the supine position with their arms above their head. The prone position can be useful for patients who are claustrophobic or who find the supine position uncomfortable. Occasionally, the prone or decubitus position can be used to more accurately define pathology. CT images obtained from the decubitus position are often useful for evaluating air-fluid or fluid collections. The prone position can be used to evaluate or facilitate biopsy of abnormalities in the retrocardiac area, such as esophageal masses and azygoesophageal lymphadenopathy (Fig. 29-7).

CT scans are performed, if possible, during a single breath-hold. When scanning is performed using narrow collimation on a single-detector-row spiral CT scanner, however, it may not be possible to complete the scan in a single breath-hold. Hyperventilation prior to scanning can improve breath-holding and thus image quality. The mediastinum, however, can be scanned in less than 10 seconds when multidetector-row spiral CT scanners are used. If the patient cannot accomplish a breath-hold for this short length of time, the scan can be performed during quiet breathing, often with good results.

Figure 29-1. Saccular aneurysm of descending aorta. *A*, Posteroanterior chest radiograph shows homogeneous soft tissue mass (arrowheads) in the left hemithorax. Acute margins at interface with mediastinum suggest intrapulmonary mass. *B*, Contrast-enhanced CT shows saccular aneurysm (arrowheads) of descending aorta (D) with peripheral thrombus.

Figure 29-2. Thymoma in woman with myasthenia gravis. Chest radiograph (not shown) was normal. Because of association between myasthenia gravis and thymoma, chest CT was performed and revealed small soft tissue mass in anterior mediastinum (arrow). Resection confirmed thymoma. A, aorta; S, superior vena cava.

Figure 29-3. Fibrosing mediastinitis. *A*, Axial CT shows marked narrowing of bronchus intermedius (arrowhead) by soft tissue attenuation mass (M) (arrows). Note extensive subcarinal calcification. D, descending aorta. *B*, Volume-rendered shaded-surface display shows long-segment irregular narrowing of bronchus intermedius (arrowheads). Three-dimensional reconstructions can facilitate assessment and treatment of airway stenoses. L, left main bronchus; R, right main bronchus; T, trachea; U, right upper lobe bronchus.

Figure 29-4. Pseudoaneurysm after repair of aortic coarctation. A–C, Contrast-enhanced CT shows pseudoaneurysm (P) at site of coarctation repair. A narrow isthmus (*arrowheads* in A) can be seen between the pseudoaneurysm and the transverse aorta, and a wide connection (*arrow* in C) can be seen between the pseudoaneurysm and the descending aorta. D, Oblique volume-rendered maximal intensity projection image clearly shows relationship of pseudoaneurysm to proximal (*arrows*) and distal (*arrowheads*) aorta as well as the brachiocephalic artery (+). Three-dimensional reconstructions of CT angiograms display anatomy in a more familiar perspective to clinicians than axial CT images. A, ascending aorta; B, brachiocephalic vein; D, descending aorta; S, superior vena cava.

Figure 29-5. Mediastinal cyst. A, CT shows well-circumscribed homogeneous mass in anterior mediastinum (arrowheads). Although the mass shows lower attenuation than the vascular structures, its appearance is not diagnostic for mediastinal cyst. A, ascending aorta; P, main pulmonary artery. B and C, Axial T1-weighted and T2-weighted MR images show mass to be of homogeneous low signal intensity on T1-weighted image (arrowheads in B) and high signal intensity on T2-weighted image (C), which is consistent with a cyst. A, ascending aorta; P, main pulmonary artery.

Figure 29-6. Non-Hodgkin's lymphoma in a patient with renal insufficiency. A, CT shows homogeneous middle and posterior mediastinal mass encasing descending aorta, anteriorly displacing the tracheal carina (arrows) and extending into the paravertebral region bilaterally (arrowheads). Small bilateral pleural effusions can be visualized. B, Cine gradient-recalled echo MR image performed to evaluate possible vascular invasion confirms flow within descending aorta. A low-signal-intensity mass (arrowheads) and a high-signal-intensity pleural effusion (P) can be seen. A, ascending aorta; D, descending aorta.

Figure 29-7. CT (extended window) performed with the patient in the prone position to improve access for biopsy of middle mediastinal mass (M). Diagnostic specimen was obtained and confirmed non-Hodgkin's lymphoma. Arrow indicates the biopsy needle.

CT Acquisition Parameters

The choice of CT acquisition parameters depends on the clinical situation and the CT scanner. Typically, CT of the mediastinum is performed at 120 to 130 kV and 200 to 300 mA. Most single-detector-row spiral CT machines use a 180-degree linear interpolation algorithm to reconstruct the individual axial slices. Any of a number of possible postprocessing reconstruction algorithms can then be applied to generate the final images. A smoothing or "soft tissue" reconstruction algorithm is used to decrease artifacts caused by abrupt changes between tissues of different density.

The field of view is usually between 34 and 50 cm and, combined with an image matrix of 512×512 , yields a pixel size of about 1 mm. Smaller fields of view (15 cm) can be used to decrease the pixel size to 0.3 mm. These techniques are usually unnecessary for routine mediastinal imaging but can be useful for imaging the central airways.

With single-detector-row spiral CT, the user must choose three parameters: (1) slice collimation, (2) pitch ratio, and (3) reconstruction interval. For routine mediastinal CT, *slice collimation* is usually set between 7 and 10 mm. For evaluation of small lesions, suspected hilar pathology, or central airway lesions, slice collimation may be decreased to 3 or 5 mm.

Pitch is defined as the ratio between table speed and slice collimation. On a single-detector-row scanner using a 180-degree linear interpolation algorithm, pitch can be increased to 2.0 without significant loss of image quality. Increasing pitch is desirable whenever possible, because increasing pitch decreases scan time proportionately. Increasing pitch beyond 2.0, however, results in unacceptable loss of longitudinal resolution. For routine mediastinal CT, the pitch selected is usually between 1.3 and 2.0.

The image *reconstruction interval* is usually chosen to be the same as, or slightly less than, slice collimation for routine axial imaging. Thus, for a routine 7-mm slice collimation scan, the reconstruction interval is usually ei-

ther 5 or 7 mm. If nonaxial 2D or 3D reconstructions are to be generated from the axial images, a minimum of 20% to 30% reconstruction overlap is needed to minimize stair-step artifacts between slices. Thus, for a 5-mm slice collimation scan, axial reconstructions should be performed at least every 2 or 3 mm.

With multidetector-row scanners, the user typically has much less flexibility in protocol selection because of the complex physics involved in the reconstruction of individual axial slices from multiple overlapping helices. User-specified parameters are typically slice collimation, table speed, and operation mode. The user does not usually specify pitch per se. Most manufacturers supply information regarding acceptable choices of slice collimation and table speed to optimize image resolution. The General Electric QXi scanner, for example, allows the user to choose one of two modes of operation: *high quality* (HQ—effective pitch = 3.0) or *high speed* (HS—effective pitch = 6.0).

When an imaging protocol is prescribed for a multidetector-row CT scanner, it is best to initially select the slice collimation. The operation mode and maximum allowable table speed are then selected. For routine mediastinal imaging, 7.5-mm collimation in HQ mode with a table speed of 11.75 mm per rotation allows evaluation of most mediastinal abnormalities. Imaging of vascular structures or airways requires narrower collimation (2.5 or 5 mm) and more rapid table speed (15 to 30 mm per rotation table speed) in high-speed mode.

Use of Contrast Medium

Most routine CT scans of the mediastinum can be performed without IV contrast enhancement unless the primary indication is a suspected vascular abnormality (Fig. 29-8). Interpretation of non-contrast-enhanced CT scans, however, can be more difficult and time-consuming than interpretation of contrast-enhanced scans and requires thorough knowledge of mediastinal anatomy and normal variants. There are, however, several advantages to non-contrast-enhanced CT scanning:

1. Scan time is decreased because there is no need to establish IV access, set up the contrast-medium injector, or delay the scan as the bolus is administered.
2. There is no risk of a reaction to contrast medium.
3. The cost is lower.

When needed, IV contrast material is given through a large forearm or antecubital vein by a power injector. Contrast injection rate and total injection volume depends on the indication. For routine purposes, a rate of 2 mL/second for a total volume of 150 mL is sufficient. For vascular imaging (aorta and pulmonary artery), higher injection rates (3 to 4 mL/second) are often necessary. In such cases, it is mandatory that injection be through a relatively large-bore IV catheter (18 or 20 gauge) into a large antecubital vein. The timing of the bolus in relationship to the scan also varies and depends on both the indication (routine versus arterial imaging) and the time required to complete the scan.

Thoracic CT is usually performed without esophageal contrast medium. Oral contrast medium can, however, be helpful in identifying the relationship between the esopha-

Figure 29-8. Aortic pseudoaneurysm after coronary artery bypass graft surgery. *A*, Non-contrast-enhanced CT performed 4 weeks after surgery to exclude mediastinitis shows heterogeneous low-attenuation mass in anterior mediastinum (*arrowheads*), suggestive of abscess. *A*, aorta. *B*, Because of the proximity of the mass to the aorta, the patient was rescanned using intravenous contrast, and the mass was shown to be a pseudoaneurysm arising from the aortic cannulation site.

gus and other mediastinal structures and occasionally, in depicting intrinsic esophageal abnormalities (Fig. 29-9). Commercial preparations of esophageal paste, made of a dilute barium mixture, are available for use. The patient must swallow several teaspoons of the paste and refrain from further swallowing during the examination.

CT Reconstruction and Image Display

CT scans of the mediastinum are usually reconstructed, filmed, and interpreted in axial format. Until recently, sagittal, coronal, and off-axis reconstructions of the thorax were not used because of slice misregistration and respiratory motion artifacts. With the advent of spiral scanning, however, continuous volume data sets can be acquired during a single breath-hold and excellent nonaxial 2D and 3D reconstructed images of mediastinal vascular structures and airways can be generated (see Figs. 29-3 and 29-4). Different reconstruction methods, such as multiplanar reformat

imaging, multiplanar volume reformat imaging, and external and internal 3D renderings, vary significantly in computational complexity and time required to generate the images.

Mediastinal CT images may be interpreted in either hard-copy (film) or soft-copy (workstation/display) format. Most axial scans are still printed and interpreted on film. When CT studies of the chest are being filmed, two different window settings are needed because of the wide range in the CT attenuation numbers of the tissues to be displayed: -800 Hounsfield units (HU) for lung and 600 HU for bone. Lung settings should have a wide width to encompass air-filled lung and soft tissue and are usually viewed at a level of -600 and a width of 1200. Because of the smaller density range between fat, soft tissue, bone, and contrast-enhanced vessels, mediastinal settings are usually viewed at a level of 50 and a width of 350.

These levels and widths can be varied to aid in the

Figure 29-9. Esophageal leiomyoma. *A*, CT shows large middle-mediastinal mass with focal punctate calcifications (*arrowheads*). The esophagus is displaced anteriorly (*arrow*). The CT appearance is nonspecific and the origin of mass is uncertain. *A*, aorta; *L*, liver; *M*, mass. *B*, CT following ingestion of oral barium reveals distortion of esophageal lumen (*asterisk*), consistent with a mass arising within the wall of the esophagus. Resection confirmed leiomyoma. *A*, aorta; *M*, mass.

evaluation of any lesion that is not adequately differentiated on the standard settings. For example, during evaluation of a mediastinal mass for subtle calcification, setting the window width on 1 and moving the level between 50 and 300 HU while one views the monitor can often aid detection. Bone windows with a wide width and a level of near 400 HU are often needed to evaluate for possible bone metastases.

Soft-copy interpretation of mediastinal CT is increasing because of the increasing use of (1) picture archiving and communications systems and (2) cine or nonaxial modes for interpretation of complex CT data sets.

MRI Techniques

Spin-Echo Imaging

In the thorax, both T1-weighted and T2-weighted spin-echo images are usually desirable when assessing soft tissue abnormalities.* Although such simple techniques are efficacious for imaging the superior aspect of the mediastinum, cardiac pulsation and respiratory motion degrade images of the lower mediastinum. Many techniques have been developed to correct or eliminate image degradation caused by motion, including:

1. Reducing apparent motion by averaging.
2. Utilizing motion correction techniques.
3. Rapidly acquiring data such that breath-holding is possible.

The simplest method for motion correction is to average the MR signal with many acquisitions. The advantage of multiple acquisitions, however, is offset by an increase in data collection times. Furthermore, for echo times of more than 10 msec, motion artifacts persist in the hilum and adjacent to the heart. Alternatively, breath-held T1-weighted spin-echo imaging using one excitation (NEX), conjugation (half NEX imaging), and short repetition times (TRs), can be used. This technique has a poor signal-to-noise ratio and, although rapid, is still too long to prevent artifacts due to cardiac contraction.

Images can be acquired in fractions of a second using echo-planar sequences. This enables motion to be "frozen" during data acquisition. Such sequences, however, require special hardware and software. More important, because of the large chemical shift between fat and water, echo-planar imaging requires suppression or excitation of either fat or water, reducing the overall contrast available.

Between these extremes of data acquisition resides cardiosynchronous spin-echo imaging using either plethysmography or electrocardiographic (ECG) gating. Image acquisition timed to the cardiac cycle improves delineation of abnormalities within the lower mediastinum and around the heart compared with noncardiosynchronous imaging. For complete assessment of cardiac function, ECG gating is preferred because the precise temporal relationship between each image and the QRS complex is known. If only anatomic information is required, however, plethysmography is generally used because of the simplicity of patient preparation.

One consequence of cardiosynchronous acquisitions is that the TR is dependent on the patient's heart rate. Consequently, the acquired images may not be as T1-weighted or T2-weighted as those obtained elsewhere in the body. For example, in a patient with a heart rate of 60 beats/minute, the effective TR is 1000 msec, resulting in images that are neither T1-weighted nor T2-weighted. With a selected echo time (TE) of 20 msec, the image is somewhat proton-density-weighted. Even if the TE is lengthened to 70, images obtained are not truly T2-weighted. To obtain such an image, the TR must be lengthened by multiples of the patient's heart rate. For example, acquiring data over every two heartbeats would increase the TR to 2000 msec. One positive consequence of lengthening the TR is the capability of acquiring images at more anatomic locations. A disadvantage, however, is the doubling of acquisition time and the potentially increased image blur.

Cardiosynchronous acquisitions reduce the effect of cardiac motion but do not compensate for respiratory motion. Respiratory gating, in which MR data are acquired only during periods of apnea, when combined with cardiosynchronous data acquisitions, can be used to improve image quality. This technique, however, is more time-consuming. Using respiratory motion correction algorithms, such as respiratory compensation, can improve image quality by displacing ghost artifacts either outside the imaged field of view or by returning them to their site of origin. These techniques are easily combined with cardiosynchronous data collection and do not significantly increase data acquisition time.

Gated RARE (fast spin-echo, turbo spin-echo) techniques can be used to provide T2-weighted contrast in a fraction of the time when compared with conventional spin-echo acquisitions.

Gradient-Recalled Echo Acquisitions

White blood techniques can be used to assess mediastinal vessels. These gradient-recalled echo (GRE) techniques, such as FLASH (fast low-angle shot) and GRASS (gradient-recalled acquisition in the steady state), render fluid as high signal because of the inflow of unsaturated protons. The stationary tissues appear dark because of their repeated excitation by multiple RF pulses. Within the soft tissues, the contrast available is dependent on the particulars of the acquisition. Either a T1-weighted acquisition (e.g., FLASH) or a more T2-weighted acquisition (e.g., GRASS) can be obtained.^{7, 28, 68, 91, 192, 253}

As with spin-echo imaging, the pulsatility of aortic flow and the respiratory motion of most patients results in unsatisfactory images in the lower mediastinum and adjacent to the heart. *Gradient moment nulling* (flow compensation) is routinely employed with such techniques but is generally insufficient to correct all motion artifacts. For complete motion correction, a cardiosynchronous GRE acquisition with respiratory compensation is usually obtained. These sequences have been dubbed *cine MRI*.

With a short TR, GRE data are acquired in 20- to 40-msec segments during the cardiac cycle. The temporal relationship of the data acquisition to the cardiac cycle is recorded and after sufficient data are obtained, a series of images with a frame rate of 10 to 40 frames per minute is

*See References 3, 13, 58, 61, 64, 92, 100, 102, 106, 139, and 152.

produced and may be viewed as a continuous loop of images through the cardiac cycle. As typically performed, two to four anatomic locations are imaged in a 3- to 5-minute acquisition, depending on the patient's heart rate. The true temporal resolution of the sequence depends on the number of anatomic locations imaged per acquisition and the patient's heart rate. The slower the patient's heart rate and the smaller the number of anatomic locations imaged per acquisition, the higher the temporal resolution. Although high temporal resolution is required for cardiac analysis, a lower frame rate is sufficient to visualize mediastinal structures, allowing more anatomic locations to be acquired per acquisition. As such, 16 anatomic locations can be acquired in 12 to 15 minutes, allowing the entire mediastinum to be covered.

The main limitation of these retrospective cine techniques is their relatively long acquisition times and their sensitivity to arrhythmias. More recently, cardiac-gated, segmented k-space acquisitions have become available. These acquisitions acquire data in a single breath-hold using prospective cardiac gating. The pulse sequence consists of a fast GRE acquisition, such as turbo-FLASH or fast GRASS. TRs are on the order of 5 to 10 msec with echo times of 1 to 3 msec. Flip angles are small, typically 15 to 30 degrees.

As with retrospective techniques, the R-to-R interval in each cardiac cycle is divided into multiple frames of 20 to 80 msec in duration. During each frame, in a fashion analogous to fast spin-echo data acquisition, a number of lines of k-space are acquired. This is referred to as the number of views per segment or the number of views per phase, and it is equivalent to *echo train length* (ETL) or TURBO factor in fast spin-echo or turbo spin-echo imaging. The more views sampled per segment, the smaller the number of R-to-R intervals required and the faster the acquisition.

For example, using eight views per segment, 128 lines of k-space can be acquired over 16 R-to-R intervals, which for most patients is a 15- to 25-second breath-hold. Assuming a TR of 10 msec, view sharing of eight frames, and a heart rate of 60 beats/minute, approximately 12 frames per cardiac cycle can be produced. If the number of frames per segment is increased, the total acquisition time is reduced; however, the number of frames per cardiac cycle is also decreased. In addition, since the data acquisition time for each frame of the cardiac cycle is increased, the amount of image blur is increased.

Although much faster than retrospective cine imaging, these segmented k-space techniques have a shorter acquisition time that is associated with a reduced signal-to-noise ratio. In our experience, a dedicated surface coil is necessary to compensate for this lower signal-to-noise ratio. A final disadvantage of these techniques is the reduced intraluminal signal that results from the slow flow seen during diastole.

Contrast-Enhanced Magnetic Resonance Angiography and Venography

Both arterial and venous anatomy can be visualized with the administration of gadolinium during the acquisition of a fast GRE volume data set. Such techniques have been

well described for visualizing the aorta, renal arteries, carotids, and portal vein. These techniques have a rapid acquisition time (10 to 30 seconds) and, as such, a complete MR angiography or MR venography can be acquired in a single breath-hold.

The clear disadvantages of such techniques are the expense of the contrast agent and the small risk of a contrast reaction. In addition, timing arrival of the contrast bolus to the structure of interest is required for optimal visualization.

Summary

Spin-echo imaging, although superb for visualizing the soft tissues, is less specific for assessing vascular patency. White blood or contrast-dependent techniques optimize the signal intensity of flowing blood. A consequence of this, however, is a reduced conspicuity of soft tissue abnormalities within the mediastinum. Consequently, it may be necessary to acquire sequences with both techniques for accurate interpretation of the study.

Normal Mediastinal Anatomy

Comprehensive knowledge of cross-sectional anatomy is required to accurately evaluate mediastinal abnormalities. Interpretation of mediastinal anatomy, however, can be assisted by analyzing CT images at specific levels within the chest that are easily identifiable because of their characteristic anatomic landmarks and appearance.

Thoracic Inlet Level

At the junction of the neck and the thorax, most of the mediastinal structures are vascular (Fig. 29-10). The two brachiocephalic veins are formed as the internal jugular veins join the subclavian veins and are located posterior to

Figure 29-10. Thoracic inlet level. The trachea (T) and esophagus (E) are midline, and they separate the right and left vascular structures. LCC, left common carotid artery; LSC, left subclavian artery; LV, left brachiocephalic vein; RCC, right common carotid artery; RSC, right subclavian artery; RV, right brachiocephalic vein.

the clavicular heads. These veins are the most anterior and lateral of the six vessels. More medially are the two common carotid arteries, and just posterior to these are the subclavian arteries. The subclavian arteries and veins exit the mediastinum to enter the axilla after crossing over the first rib. The esophagus is posterior or posterolateral to the trachea. There are six major vessels at this level.

Left Brachiocephalic Vein Level

The left brachiocephalic vein crosses the midline anterior to the arterial branches of the aorta and joins the more vertically orientated right brachiocephalic vein to form the superior vena cava (SVC). (Fig. 29-11). The internal mammary veins can often be identified coursing posteriorly from a parasternal location to join the brachiocephalic veins.

The right brachiocephalic, left common carotid, and left subclavian arteries are located posterior to the left brachiocephalic vein and anterior to the trachea. The right brachiocephalic artery is the more centrally located artery, whereas the left common carotid artery (the smallest of the three arteries) and the left subclavian artery are located to the left of the midline in a more lateral and posterior position.

The esophagus is posterior or posterolateral to the trachea and anterior to the spine.

Aortic Arch Level

The transverse arch crosses the mediastinum anterior to the trachea coursing obliquely from right to left and from anterior to posterior (Fig. 29-12). The SVC is located adjacent to the anterior aspect of the transverse aorta to the right of the trachea. The fat-filled region posterior to the SVC, anterior to the trachea, and lateral to the aorta is the pretracheal space. Anterior to the transverse aorta is the fat-filled prevascular space, a compartment of the ante-

Figure 29-11. Left brachiocephalic vein level. Right (RV) and left (LV) brachiocephalic veins are anterior to right brachiocephalic artery (BC), left common carotid artery (LCC), and left subclavian artery (LSC).

Figure 29-12. Aortic arch level. Superior vena cava (S) and aortic arch (ARCH) lie anterior to the trachea (T) and esophagus (E). The thymus, which has undergone fatty infiltration, is anterior to the arch.

rior mediastinum that extends cephalad anterior to the great vessels of the aorta and the brachiocephalic veins. If present, the thymus gland is located in this space. Both of these spaces often contain a few small lymph nodes.

The esophagus is posterior or posterolateral to the trachea and anterior to the spine.

Azygos Arch and Aortopulmonary Window Level

The azygos vein, located anterior and slightly to the right of the spine, arches anteriorly and joins the SVC at this level (Figs. 29-13 and 29-14). The azygos arch may not be seen in its entirety on one slice and may be confused with lymphadenopathy. The ascending and descending aorta are visible as separate structures at this level. The

Figure 29-13. Arch of the azygos vein or the aortopulmonary (AP) window level. Azygos vein (AZ) arches from a posterior position along the midesophagus to join the superior vena cava (S), crossing over the right upper lobe bronchus. Between the ascending (A) and descending (D) aorta is the AP window region. E, esophagus; T, trachea.

Figure 29-14. Aortopulmonary (AP) window level. AP window is between ascending (A) and descending (D) aorta. SVC, superior vena cava.

ascending aorta is anterior to the trachea, and the descending aorta is posterolateral to the trachea on the left. Typically, the ascending aorta (mean diameter, 3.5 cm) is larger than the descending aorta (mean diameter, 2.5 cm).

The aortopulmonary window is a space located between the inferior aspect of the aortic arch and the superior aspect of the left main pulmonary artery. In some patients, the close anatomic contiguity of these two structures prevents visualization of this space. The space is otherwise fat-filled and contains a few small lymph nodes, the left recurrent laryngeal nerve, and the ligamentum arteriosum.

The esophagus is posterior to the trachea, anterior to the spine, and medial to the descending aorta.

Left Pulmonary Artery Level

The main pulmonary artery is anterior and to the left of the ascending aorta. The left pulmonary artery curves posteriorly from its origin from the main pulmonary artery and is located anterolateral to the left main bronchus at the level of the carina (Figs. 29-15 and 29-16). The left superior pulmonary veins are located lateral to the posterior portion of the left pulmonary artery.

On the right, at the level of the carina, is the origin of the right upper lobe bronchus. Anterior to the right upper lobe bronchus lies the right upper lobe pulmonary artery or the truncus anterior. The right superior pulmonary veins are located anterior and lateral to the truncus anterior. The azygos vein is located posterior and to the right of the esophagus. The hemiazygos vein parallels the course of the azygos but is to the left of the spine.

The superior pericardial recess, a crescent-shaped extension of the pericardial space, is contiguous with the posterior aspect of the ascending aorta. The space often contains a small amount of fluid and can occasionally be confused with a lymph node. Its characteristic location, shape, and low attenuation, however, allow confident identification.

The concave extension of right lung into the mediastinum anterior to the spine is the azygoesophageal recess, which extends inferiorly from the subcarinal region to the level of the diaphragm.

Figure 29-15. Left pulmonary artery level. To the left of the left pulmonary artery (LPA) lie the left superior pulmonary veins. The ascending (A) and descending (D) aorta and superior vena cava (S) maintain their relative positions from the level above. The truncus anterior (TA), or right upper lobe pulmonary artery, is anterior to the right upper lobe bronchus. The azygoesophageal recess (AZE) is a concavity anterior to the spine.

Right Pulmonary Artery Level

The main pulmonary artery is anterior and to the left of the ascending aorta (Figs. 29-17 and 29-18). The right pulmonary artery extends posteriorly and to the right from the main pulmonary artery, passing anterior to the bronchus intermedius and posterior to the SVC. The right superior pulmonary vein is to the right and lateral to the intrapulmonary portion of the right pulmonary artery. Anterior to the left main and upper lobe bronchi is the left superior pulmonary vein, and posterior to the left upper lobe bronchus is the left lower lobe pulmonary artery.

Left Atrial Level

The anatomy of the mediastinum is complex at this level (Figs. 29-19 and 29-20). Anterior to the SVC is the

Figure 29-16. Left pulmonary artery level. The superior pericardial recess (SPR) is an extension of the pericardium. A, ascending aorta; D, descending aorta; LPA, left pulmonary artery; S, superior vena cava.

Figure 29-17. Right pulmonary artery level. The main pulmonary artery (PA) divides into the left (LPA) and right (RPA) pulmonary arteries. The right pulmonary artery passes anterior to the right main bronchus, and the left pulmonary artery passes over the left main bronchus. A, ascending aorta; D, descending aorta; S, superior vena cava.

right atrial appendage curving around the ascending aorta. The aorta is located centrally within the mediastinum, and anterior and to the left of the aorta is the pulmonary outflow tract. Posterolateral and to the left of the pulmonary outflow tract is the left atrial appendage. Within the fat, between the left atrial appendage and the aortic root, is the left main coronary artery. The left superior pulmonary vein enters the left atrium immediately posterior to the left atrial appendage. The right superior pulmonary veins enter the left atrium just posterior to the SVC.

Four-Chamber Level

All four chambers of the heart are identified at this level (Figs. 29-21 and 29-22). The posteriorly located left

Figure 29-18. Right pulmonary artery level. The main pulmonary artery (MPA) divides into the right pulmonary artery (RPA) and the left pulmonary artery, which is more superior and not visible. The left superior pulmonary vein (LSPV) is anterior to the left main bronchus, and the left pulmonary artery (PA) is posterior. The superior aspect of the right atrial appendage (RAP) is anterior to the superior vena cava (S). A, ascending aorta; D, descending aorta.

Figure 29-19. Left atrial level. The left atrium (LA) is the most superior and posterior chamber of the heart. Superior pulmonary veins enter the anterosuperior portion of the left atrium. The left atrial appendage (LAP) is situated anterior and to the left of the left atrium, adjacent to main pulmonary artery (P). The right atrial appendage (RAP) is anterior to superior vena cava (SVC) and adjacent to ascending aorta (A). D, descending aorta; LPA, left pulmonary artery; RPA, right pulmonary artery; RSPV, right superior pulmonary vein.

atrium is the most cranial of all the chambers. The right and left inferior pulmonary veins enter the posterolateral aspect of the left atrium. Anterior and to the right is the right atrium. To the left and anterior to the right atrium is the right ventricle located behind the sternum. The left ventricle is to the left and posterior to the right ventricle.

The coronary arteries can be detected if they are calcified or if fat surrounds the heart. The right coronary artery lies in the right atrioventricular groove. The circumflex coronary artery lies in the left atrioventricular groove, and the left anterior descending coronary artery lies in the intraventricular groove between the left and right ventricles.

Figure 29-20. Left atrial level. A, aortic root; IPV, left inferior pulmonary vein; LA, left atrium; LPA, left lower lobe pulmonary arteries; RA, right atrium; RPA, right lower lobe pulmonary artery; RV, right ventricle.

Figure 29-21. Four-chamber level. The right coronary artery (RCA) is visible in the right atrioventricular groove. A, aortic root; D, descending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 29-23. Three-chamber level. The left atrium is more cranial to this level and is not visible. The three visualized chambers are right atrium (RA), the right ventricle (RV), and the left ventricle (LV). The coronary sinus (CS) is between the inferior vena cava (I) and the left ventricle. A, descending aorta; AZ, azygos vein.

Three-Chamber Level

The ventricles and the right atrium are identified at this level (the left atrium, because of its more cranial position, is not visible) (Figs. 29-23 and 29-24). The right atrium is located to the right. To the left and anteriorly, the right ventricle with its thin wall is located just beneath the sternum. The thick-walled left ventricle makes up the posterolateral left portion of the mediastinum. Between the left ventricle and the inferior vena cava's opening into the right atrium is the coronary sinus.

MR Images of the Mediastinum

The standard spin-echo, T1-weighted axial images of the mediastinum are similar in appearance to CT images (Figs. 29-25 to 29-29). However, signal void of the airways can occasionally be confused with the lack of signal in vessels. Coronal and sagittal MR images are helpful in depicting the anatomic relationships of normal mediastinal

structures as well as in identifying and locating pathology (Figs. 29-30 to 29-34).

Mediastinal Divisions

The mediastinum extends craniocaudally from the thoracic inlet to the diaphragm and, historically, has been divided into compartments (on the chest radiograph) to facilitate lesion localization and aid in diagnosis. This division of the mediastinum into anatomic regions or compartments is still important but not essential because CT and MRI can accurately localize and, in many instances, characterize masses. Despite these advances, however, mediastinal masses are still discussed, classified, and grouped by their position on chest radiographs.

In this chapter, we use the widely accepted division of the mediastinum into superior, anterior, middle, and posterior compartments.

The *superior mediastinum* is the space between the

Figure 29-30. Anterior coronal MR image. A, ascending aorta; LV, left ventricle; P, main pulmonary artery; RA, right atrium.

Figure 29-31. Coronal MR image at the right pulmonary artery level. A, aorta; I, inferior vena cava-right atrial junction; L, left pulmonary artery; LA, left atrium; RPA, right pulmonary artery; T, trachea.

thoracic inlet and the superior aspect of the aortic arch (i.e., all mediastinal structures above an imaginary line drawn between the sternal angle and the fourth intervertebral disk on the lateral chest radiograph).

The *anterior mediastinum* is the space anterior to the heart and great vessels on the lateral chest radiograph. It is bordered anteriorly by the sternum and posteriorly by the pericardium. Using this designation, normal anterior mediastinal structures include the thymus, the branches of the internal mammary artery and vein, lymph nodes, and fat.

Controversy exists concerning the division between the middle and the posterior mediastinum. Some authors suggest that the division should be the posterior aspect of the pericardium, but others would divide the two by an imaginary line drawn 1 cm posterior to the anterior border of

Figure 29-33. Sagittal MR image of the main pulmonary artery. AO, aorta; LA, left atrium; PA, main pulmonary artery; RV, right ventricle.

the vertebral bodies. The latter method places most aortic and esophageal lesions in the middle mediastinum and reserves the posterior mediastinum for neurogenic or other paraspinal lesions. Other methods involve dividing the middle and posterior mediastinum on the basis of the azygos arch and the aorta.

For purposes of this discussion, we define the *middle mediastinum* as the space between the anterior border of the pericardium and an imaginary line drawn 1 cm posterior to the anterior border of the vertebral bodies on the lateral radiograph. As such, it contains the heart, the aorta, the superior and inferior venae cavae, the brachiocephalic arteries and veins, the pulmonary arteries and veins, the thoracic duct, the azygos and hemiazygos veins, the phrenic and vagus nerves, the trachea and proximal bronchi, mediastinal fat, and lymph nodes.

The *posterior mediastinum* is defined as the space be-

Table 29-1. Classification of Mediastinal Abnormalities by Compartment Affected

Location	Lesion
Superior mediastinum	Thyroid goiter, tortuous great vessels
Anterior mediastinum	Thymic lesions, germ cell tumors, parathyroid adenoma, lymphatic malformations, hemangioma
Middle mediastinum	Esophageal lesions, airway lesions, foregut cysts, pericardial cysts
Posterior mediastinum	Neurogenic tumors, paraspinal abscess, extramedullary hematopoiesis
Multiple compartments	Mediastinitis, lipomatosis, lymphadenopathy (lymphoma, metastases, Castleman's disease, infection), mesenchymal tumors, vascular abnormalities and anomalies, diaphragmatic hernias

tween the imaginary line drawn 1 cm posterior to the anterior border of the vertebral bodies and the posterior paravertebral gutters. Structures in the posterior mediastinum include nerves, fat, the vertebral column, and lymph nodes.

Mediastinal Abnormalities

A useful approach for discussing mediastinal abnormalities is to divide them into those processes that predominantly affect *specific* compartments (superior, anterior, middle, and posterior mediastinum) and those processes that can affect *multiple* compartments (Table 29-1). An alternative method of classifying mediastinal masses is on the basis of their predominant attenuation characteristics on CT rather than by their location (Table 29-2).^{86, 87} We will use the *former* approach in this discussion.

Table 29-2. Classification of Mediastinal Abnormalities Based on CT Attenuation Characteristics

CT Attenuation	Lesion
Fat	Lipoma, lipomatosis, thymolipoma, liposarcoma, teratoma, epicardial fat pad, hernia
Water	Thymic cyst, teratoma, pericardial cyst, bronchogenic cyst, esophageal duplication cyst, meningocele, neurenteric cyst
Soft tissue	Thymoma, thymic carcinoma, germ cell tumor, esophageal neoplasm, neurogenic tumor, lymphoma, lymphadenopathy
High attenuation	Calcified nodes (histoplasmosis, tuberculosis, sarcoidosis, silicosis), calcified neoplasm (thymoma, teratoma, treated lymphoma, metastases), fibrosing mediastinitis, hemorrhage, goiter, vascular
Contrast-enhancing	Vascular, goiter, Castleman's disease, hemangioma, paraganglioma

Superior Mediastinal Abnormalities

Common superior mediastinal abnormalities include intrathoracic extension of thyroid goiters or masses and tortuous great vessels.

Thyroid Goiter

On CT, the normal thyroid gland is typically visible at or just below the level of the cricoid cartilage (Fig. 29-35). It appears on a non-contrast-enhanced CT scan as two wedge-shaped structures of homogeneous attenuation on either side of the trachea, separated by a narrow anterior isthmus. Its attenuation is usually increased, compared with that of muscle, because of the iodine content of the gland. It typically enhances homogeneously following administration of IV contrast material. On MR images, the normal thyroid gland usually has intermediate signal intensity, slightly greater than the adjacent muscle, on T1-weighted

Figure 29-35. Normal thyroid gland. A, Contrast-enhanced CT shows typical appearance of thyroid gland (arrows). Enhancement is homogeneous. T, trachea. B, T1-weighted axial MR image shows homogeneous intermediate signal intensity typical of normal thyroid gland (arrows). T, trachea.

Figure 29-36. Thyroid goiter. A, CT shows heterogeneous superior mediastinal mass (arrowheads) with punctate calcification. Images at thoracic inlet (not shown) confirmed contiguity of mass with the left thyroid lobe, consistent with intrathoracic extension of goiter. B, Contrast-enhanced CT shows heterogeneous enhancement of mass. T, trachea.

images and higher signal intensity on T2-weighted images (see Fig. 29-35).

Most thyroid masses in the mediastinum are caused by intrathoracic extension of thyroid goiters, which can account for up to 10% of mediastinal masses resected at thoracotomy. True ectopic thyroid masses in the mediastinum are rare. Typically, a thyroid goiter extends into the thyropericardiac space anterior to the recurrent laryngeal nerve and brachiocephalic vessels, although posterior extension adjacent to the trachea occurs in 20%. Rarely, thyroid masses may extend behind the esophagus and present as a posterior mediastinal mass.

A mediastinal goiter is usually detected on chest radiographs as a thoracic inlet or superior mediastinal mass that deviates and occasionally narrows the trachea.^{20, 78, 84, 105, 107, 132, 227} Although scintigraphy can detect mediastinal goiters, the uptake of technetium or iodine is variable. The CT appearance of a mediastinal goiter is variable, but the goiter can be confidently diagnosed when continuity of the mass with the thyroid gland is visible. Additional features useful in establishing the diagnosis include the following:

1. Heterogeneous attenuation with areas of both high and low attenuation on non-contrast-enhanced scans.
2. Marked enhancement following administration of IV contrast material.
3. Focal punctate or curvilinear calcifications (Figs. 29-36 and 29-37).

The cystic and adenomatoid composition of goiters results in a heterogeneous appearance on both T1-weighted and T2-weighted MR images (Fig. 29-38). On T1-weighted images, goiters may show lower signal intensity than normal thyroid, but high signal intensity can be seen in areas of subacute hemorrhage, colloid cysts, and adenomas. Goiters show high signal intensity on T2-weighted images.

Tortuous Great Vessels

Tortuosity of the great vessels is a common cause of a superior mediastinal abnormality on a chest radiograph. The most common location of the radiographic abnormality is in the right paratracheal region because the right brachiocephalic artery in older patients often has a tortuous course before giving rise to the right subclavian and common carotid arteries. CT without contrast enhancement can often determine that the tortuous vessels are the cause of the apparent mass. Calcification within the vessel walls allows confident identification of tortuous arteries. If any doubt exists as to the vascular nature of the mass, IV contrast enhancement easily identifies the vessels (Fig. 29-39).

Figure 29-37. Mediastinal goiter. Contrast-enhanced CT shows large goiter (G) displacing the trachea to the right, and the left common carotid and subclavian arteries to the left. Enhancement is heterogeneous.

Figure 29-38. Mediastinal goiter. Coronal MR image shows mediastinal thyroid tissue (T) on both sides of trachea, which is deviated to the right at the thoracic inlet.

Anterior Mediastinal Abnormalities

Approximately half of all mediastinal masses occur in the anterior mediastinum. Lesions that occur preferentially in the anterior mediastinum include thymic lesions (cysts, thymolipoma, thymoma, thymic carcinoma), parathyroid adenoma, germ cell tumors, hemangioma, and lymphatic malformations.^{34, 243} Lymphoma is another common cause of an anterior mediastinal mass, but it will be considered in the section on diffuse mediastinal disease.

Thymic Lesions

Normal Thymus

The thymus is a bilobed, triangular gland that occupies the thyropericardiac space of the anterior mediastinum and extends inferiorly to the heart.^{17, 49, 70, 182, 238} The normal morphology and size of the thymus change markedly with

Figure 29-39. Tortuous great vessels. Contrast-enhanced CT shows tortuous right brachiocephalic and subclavian artery (SC) causing a right paratracheal "mass." Calcifications can be seen within the arterial wall.

age.¹⁷² Wide variation exists in the normal size of the thymus, particularly in children and young adults. In the newborn, the thymus gland is often larger than the heart. Thymic size decreases with age as the gland undergoes fatty infiltration. The atrophied thymus is often visualized on CT in patients in their fourth decade of life, but it is seen in fewer than 50% of patients over 40 years of age (Fig. 29-40).

The most useful measurement is the thickness of the lobes measured perpendicular to the long axis of the gland. The normal maximal thickness is 18 mm before age 20 years and 13 mm in older patients. Although these measurements are useful indicators of thymic abnormality, thymic shape is also important; focal contour abnormality of the thymus gland is a finding suggestive of an underlying abnormality.

On CT scans, the normal thymus manifests as a homogeneous, bilobed structure of soft tissue attenuation in the anterior mediastinum (Fig. 29-41). It is usually seen at the level of the aortic arch and the origin of the great vessels. The left lobe is usually slightly larger than the right. Rarely, a lobe is congenitally absent. The normal thymus is easily demonstrated on MRI (Fig. 29-42).

Characteristically, the thymus is homogeneous with intermediate signal intensity (less than that of fat) on T1-weighted images. Because the thymus begins to involute at puberty and is replaced by fat in older patients, the T1-weighted signal intensity of the thyroid increases with age. On T2-weighted images, the thymus shows high signal intensity similar to fat in all age groups and this can make its identification difficult in patients with abundant mediastinal fat.

Thymic masses, on occasion, can be difficult to distinguish from normal thymus.²⁴⁴ Two important rules should be remembered:

1. Thymic masses usually manifest on CT or MRI as round masses and do not conform to the shape of the normal thymus.
2. Thymic masses usually show heterogeneous attenuation on CT with areas of decreased attenuation and possibly calcification.

Thymic Hyperplasia

Thymic hyperplasia can occur in association with hyperthyroidism, acromegaly, Addison's disease, and stress and in patients receiving chemotherapy or radiation therapy.^{22, 79, 94, 153}

Differentiating between hyperplasia and other causes of thymic enlargement can be difficult as there are no specific CT attenuation or MR signal intensity characteristics associated with hyperplasia. Thymic rebound or hyperplasia occurs in patients after chemotherapy or radiation therapy and it can be difficult to distinguish this enlargement from recurrent tumor. Generally, with rebound hyperplasia, the thymus has a normal shape and shows homogeneous attenuation on CT or homogeneous signal intensity on MR images (Fig. 29-43; see Fig. 29-40B). Asymmetry of the lobes, focal contour abnormalities, and heterogeneous signal intensity on MR or CT are suggestive of tumor.

Figure 29-40. Thymus gland in a 42-year-old woman with breast carcinoma. *A*, Contrast-enhanced CT shows fatty replacement of thymus gland. Residual thymic tissue manifests as linear areas of soft tissue in anterior mediastinal fat (arrow). *B*, Non-contrast-enhanced CT 6 months after bone marrow transplantation shows increased soft tissue in anterior mediastinum, consistent with thymic hyperplasia (arrow). A, aorta; S, superior vena cava.

Figure 29-41. Normal thymus gland in a 17-year-old girl. *A* and *B*, Contrast-enhanced CT shows normal thymus gland in anterior mediastinum (arrowheads). Homogeneous attenuation, smooth contours, and close association of lobes to vascular structures in the anterior mediastinum can be seen. A, aorta; P, main pulmonary artery; S, superior vena cava.

Figure 29-42. Normal thymus in 9-month-old child with coarctation of the aorta. Axial T1-weighted MR image shows thymus gland (arrowheads) in the mediastinum anterior to the aorta with homogeneous, intermediate signal intensity less than that of fat. The arrow indicates aortic coarctation. A, aorta; S, superior vena cava. (Case courtesy of Donald Frush, M.D., Duke University Medical Center, Durham, NC.)

Figure 29-43. Thymic rebound. A, CT at the time of chemotherapy. The thymus (T) is small. B, CT after cessation of chemotherapy shows that the thymus (T) has increased in size.

Thymic Cysts

Thymic cysts comprise approximately 3% of all anterior mediastinal masses and are either congenital or secondary to inflammation or malignancy (Hodgkin's lymphoma, seminoma, thymic carcinoma).^{18, 47, 89, 112, 118, 153, 168, 243, 246}

Congenital thymic cysts most likely arise from remnants of the thymopharyngeal duct and are usually thin-walled, unilocular lesions less than 6 cm in diameter. On CT, they are homogeneous, show the attenuation of water, and have very thin or imperceptible walls. On MRI, they manifest as well-circumscribed, anterior mediastinal masses of high signal intensity on T2-weighted images. Signal intensity usually increases with increasing TR. Occasionally, thymic cysts appear as solid masses on CT because they are filled with proteinaceous fluid. In these cases, MRI can be useful for confirming the cystic nature of the lesion (Fig. 29-44).

Acquired thymic cysts occur in the setting of inflammation or malignancy. Associated malignancies include Hodgkin's lymphoma, seminoma, thymoma, and thymic carcinoma (Fig. 29-45). These cysts usually have walls of variable thickness, are multilocular, and range in size from 3 to 17 cm in diameter. These cysts can contain hemorrhage or calcification. As such, the CT and MR features of acquired thymic cysts are more variable than those of congenital thymic cysts.

Because of their association with thymic neoplasia, care must be taken in the interpretation of cystic lesions of the anterior mediastinum (see Fig. 29-45). A thymic cyst must be evaluated further (by biopsy or resection) to exclude malignancy if it fits any of the following descriptions:

- Multilocular
- Heterogeneous
- Thick-walled
- Associated with a soft tissue component

Thymolipoma

Thymolipomas are rare, benign, slowly growing neoplasms of the anterior mediastinum.^{153, 213, 232, 267} They occur with equal incidence in men and women and, although the age range of presentation is wide, most are diagnosed in

young adults. On CT, these masses are typically large, show the attenuation of homogeneous fat, and conform to adjacent structures. They are not locally invasive although compression of adjacent structures occurs in approximately 50% of patients. Because they consist of fat and residual thymic tissue, thymolipomas usually show high signal intensity (similar to fat) with interspersed areas of intermediate signal intensity on both T1-weighted and T2-weighted MR images.

Thymoma

Thymomas account for approximately 20% of all mediastinal tumors and are the most common primary tumor of the anterior mediastinum.* Seventy-five percent of thymomas occur in the anterior mediastinum, 15% occur in both the anterior and superior mediastinum, and 6% occur in the superior mediastinum. Another 4% occur ectopically, with the posterior mediastinum being the least common location.

Although thymomas can occur in children, most patients are older than 40 years at presentation. Seventy percent of affected patients present in the fifth and sixth decades of life. The incidence in men and women is the same. Most affected patients are asymptomatic at presentation, and the lesion is detected on routine chest radiographs. Chest pain, cough, and symptoms related to compression of adjacent structures occur in approximately 33% of patients.

Paraneoplastic syndromes are common and include myasthenia gravis (50%), hypogammaglobulinemia (10%), and pure red blood cell aplasia (5%). Although up to 50% of patients with thymoma have myasthenia gravis, only 10% to 20% of patients with myasthenia gravis have a thymoma; however, 65% of these patients have lymphoid hyperplasia of the thymus. Because of the strong association between myasthenia gravis and thymoma, CT is commonly performed in patients with symptoms of myasthenia gravis even if the chest radiograph is normal.

Thymomas are usually 5 to 10 cm in diameter and are

*See References 60, 150, 153, 173, 178, 212, 217, 243, 250, 254, and 264.

Figure 29-44. Congenital thymic cyst. Contrast-enhanced CT (A) shows homogeneous, water-attenuation cyst (asterisk) in the anterior mediastinum. Note absence of perceptible walls and residual right thymic lobe (arrow). MR images obtained more caudally show that the mass (arrowheads) is homogeneous and of low signal intensity on the T1-weighted image (B) and of high signal intensity on the T2-weighted image (C). The MRI appearance is typical of a cyst. A, ascending aorta; P, main pulmonary artery; S, superior vena cava; T, trachea; TA, transverse aorta.

Figure 29-45. Seminoma associated with a thymic cyst. A, Contrast-enhanced CT shows well-circumscribed water-attenuation mass in anterior mediastinum. The wall (arrowheads) is thin but perceptible. B, A more cephalic image reveals a soft tissue component of the mass (arrow). Resection revealed the seminoma. T, trachea.

Figure 29-46. Thymoma in a patient with myasthenia gravis. *A*, Posteroanterior chest radiograph shows mass in the right cardiophrenic angle (arrowheads). *B*, Contrast-enhanced CT confirms well-circumscribed heterogeneous cardiophrenic-angle mass (arrowheads). Resection revealed the thymoma.

well marginated, smooth or lobulated mediastinal masses that characteristically arise from one lobe of the thymus. They are usually located anterior to the aortic arch but can occur in the cardiophrenic angle (Fig. 29-46). Most lesions are homogeneous, but necrosis and hemorrhage occur in up to one third.

On CT or MRI scans, thymomas typically manifest as smooth or lobulated masses that distort the normal contour of the thymus (Fig. 29-47). They are typically unilateral masses, although bilateral mediastinal involvement can occur. On CT they can manifest as homogeneous or heterogeneous soft tissue-attenuation masses. Intratumoral cysts or areas of necrosis may be seen. Enhancement following IV administration of contrast material is variable. Calcification, seen in up to 7% of cases, is usually thin, linear, and located in the capsule. On MR images, thymomas manifest with low to intermediate signal intensity (similar to skeletal

muscle) on T1-weighted images and high signal intensity on T2-weighted images. Because up to 33% of thymomas have focal areas of necrosis, hemorrhage, and cystic change, the masses can have heterogeneous signal intensity. MRI can occasionally reveal fibrous septa within the masses.

Up to 34% of thymomas show local invasion. Such lesions are best termed invasive thymomas rather than malignant thymomas. Histologic features and size do not seem to affect the propensity for invasive behavior. Furthermore, it can be quite difficult to predict biologic behavior of thymomas on the basis of CT or MRI findings alone. Surgical exploration is the most reliable means of determining invasion. Findings that suggest invasive thymoma on CT or MRI include the following (Figs. 29-48 to 29-50):

1. Poorly defined or infiltrative margins.
2. Definite vascular or chest wall invasion.
3. Irregular interface with adjacent lung.
4. Evidence of spread to ipsilateral pleura.

Pleural spread manifests either as isolated pleural nodules ("drop metastases") or as a contiguous pleural mass, often mimicking mesothelioma. Transdiaphragmatic spread may occur; hence, staging MR or CT studies should include the upper abdomen. Pleural effusion is uncommon despite the frequent occurrence of pleural metastases.

Thymic Carcinoma

Thymic carcinomas account for 20% of thymic tumors.^{51, 60, 97, 142, 182, 201, 243, 263} They are aggressive malignancies that often exhibit marked local invasion and early dissemination to regional lymph nodes and distant sites. Distant metastases (to lung, liver, brain, and bone) are detected in 50% to 65% of patients at presentation. Tissue studies typically reveal squamous cell carcinoma and lymphoepithelioma-like carcinoma. Symptoms (chest pain, dyspnea, cough, SVC syndrome) are usually the result of

Figure 29-47. Thymoma. Contrast-enhanced CT shows large anterior mediastinal mass (M) anterior to aorta and pulmonary artery. Main pulmonary artery is displaced posteriorly.

Figure 29-48. Invasive thymoma in a patient with symptoms of superior vena cava (SVC) obstruction. Axial T1-weighted MR images show infiltrative soft tissue mass (arrowheads) of intermediate signal intensity encasing the aorta and extending into the SVC (arrow). A, aorta. (From Erasmus JJ, McAdams HP, Donnelly LF, Spritzer CB: MR imaging of mediastinal masses. *Magn Reson Imaging Clin North Am* 8:59-89, 2000.)

Figure 29-49. Invasive thymoma. A and B, Contrast-enhanced CT shows heterogeneous anterior mediastinal mass with focal areas of calcification. Note mass extension between superior vena cava (asterisk) and ascending aorta (Ao in A) and contiguous extension to hemidiaphragm (arrowheads in B). L, liver.

Figure 29-50. Invasive thymoma with pleural metastases. A and B, Contrast-enhanced CT shows lobular heterogeneous mass (arrowheads in A) in anterior mediastinum. Noncontiguous pleural metastases ("drop metastases") (arrowheads in B) are present in the left hemithorax.

compression or invasion of adjacent structures and, unlike thymomas, paraneoplastic syndromes are rare.

Radiologically, thymic carcinomas usually manifest as large, poorly margined anterior mediastinal masses and are frequently associated with intrathoracic lymphadenopathy and pleural and pericardial effusions. Focal pleural implants are uncommon. On CT, they usually show heterogeneous attenuation and have poorly defined, infiltrative margins (Fig. 29–51). On MRI, they typically show intermediate signal intensity (slightly higher than skeletal muscle) on T1-weighted images and high signal intensity on T2-weighted images. Signal intensity can be heterogeneous because of hemorrhage and necrosis within the masses. MRI can be helpful for revealing local soft tissue and vascular invasion.

Neuroendocrine Tumors of the Thymus

Neuroendocrine tumors are uncommon lesions of the anterior mediastinum.^{34, 35, 131, 132, 211} These tumors have varying malignant potential that ranges from relatively benign (thymic carcinoid) to highly malignant (small cell carcinoma of the thymus). Thymic carcinoid tumor is the most common of this group of tumors. Affected patients are typically in the fourth and fifth decades of life; there is a male predominance. Up to 50% of affected patients have hormonal abnormalities and up to 35% have Cushing's syndrome because of tumoral production of adrenocorticotrophic hormone (ACTH). Nonfunctioning thymic carcinoids may be seen in association with the multiple endocrine neoplasia syndrome, type 1.

Radiologically, these tumors typically manifest as large masses with a propensity for local invasion. Focal areas of necrosis and punctate calcification may be present. On CT or MRI, the masses usually show heterogeneous attenuation or signal intensity, respectively (Fig. 29–52).

Germ Cell Tumors

Germ cell tumors (teratomas, seminomas, embryonal carcinomas, endodermal sinus tumors, and choriocarcinoma-

Figure 29–51. Thymic carcinoma. Contrast-enhanced CT shows heterogeneous mass in anterior mediastinum. Low-attenuation regions are consistent with necrosis. A, aorta; S, superior vena cava.

Figure 29–52. Thymic carcinoid. Contrast-enhanced CT shows large anterior mediastinal mass. The mass appears heterogeneous, and infiltration of mediastinum can be seen, with extension of the mass between vascular structures. A, aorta; S, superior vena cava.

mas) are thought to arise from mediastinal remnants of embryonal cell migration.^{50, 143, 148, 149, 187, 188, 214, 243, 258} They comprise 10% to 15% of anterior mediastinal tumors. The mediastinum is the most common extragonadal primary site of these lesions, and mediastinal lesions account for 60% of all germ cell tumors in adults. Germ cell tumors usually occur in young adults (mean age, 27 years). Most malignant germ cell tumors (>90%) occur in men, whereas benign lesions (mature teratomas) occur with equal incidence in men and women.

Mediastinal Teratoma

Teratomas, the most common mediastinal germ cell tumors, are composed of elements that arise from more than one of the three primitive germ cell layers.^{46, 72, 108, 149, 170, 187, 216, 220, 243} These tumors are classified as (1) mature, (2) immature, or (3) malignant.

Mature or benign teratomas are composed of different tissue types (ectoderm, endoderm, mesoderm), with ectodermal derivatives predominating. The term *dermoid cyst* is commonly applied to the tumors in which the ectodermal components predominate. Mature teratomas are common, accounting for 70% of germ cell tumors in childhood and 60% of mediastinal germ cell tumors in adults. Mature teratomas occur most frequently in children and young adults. Patients can be asymptomatic, but chest pain, dyspnea and cough, caused by compression of adjacent structures, are common symptoms. By definition, patients with mature teratoma have normal serum levels of β -human chorionic gonadotropin hormone (β -hCG) and alpha-feto-protein (AFP); elevation of either of these markers implies a malignant component. Complete resection is the treatment for teratomas and results in a complete cure. Although they are benign, these tumors may be difficult to remove because they are adherent to local structures.

Teratomas typically occur in the anterior mediastinum, although occurrence at other sites, including the middle and posterior mediastinum, accounts for up to 20% of cases. Mature teratomas manifest on CT or MRI as smooth

Figure 29-53. Mature teratoma. Contrast-enhanced CT shows large anterior mediastinal mass (arrowheads). The mass, which is composed of fat, calcium, and fluid, is heterogeneous in attenuation. The CT appearance is typical of a mature teratoma. A, ascending aorta; D, descending aorta.

or lobulated mediastinal masses that typically have cystic and solid components, whereas malignant teratomas are usually poorly margined masses containing areas of necrosis.

The combination of fluid, soft tissue, calcium, or fat is diagnostic of a teratoma (Fig. 29-53); the finding of a fat-fluid level within a mass on CT or MRI is also diagnostic. Fat occurs in up to 75% of mature teratomas and up to 40% of malignant teratomas; however, only 17% to 39% of mature teratomas have all the tissue components, and approximately 15% of mature teratomas manifest only a unilocular or multilocular cystic component (Fig. 29-54). Because of the varying composition of soft tissue, fat, calcium, and hemorrhage, MRI typically demonstrates heterogeneous signal intensity and this finding can be useful in differentiating teratomas from thymomas and lymphomas.

Figure 29-54. Mature teratoma. CT shows a large, predominantly water-attenuation, anterior mediastinal mass with a small focal area of fat (arrow). Mass effect can be visualized on the superior vena cava (S) and the superior pulmonary vein (arrowheads). A, ascending aorta.

Mature teratomas have been reported to rupture into lung, pleural space, and pericardium in up to 33% of patients, and CT or MRI can be useful in detecting fat within these regions.

Seminoma

Seminoma is the most common pure histologic type of malignant mediastinal germ cell tumor in men and accounts for 40% of such tumors.^{10, 143, 175, 177, 231, 243} Affected patients are usually in the third and fourth decades of life and are symptomatic at presentation. β -hCG and AFP levels are normal; elevation of AFP indicates a nonseminomatous component of the tumor. On CT or MRI, seminomas manifest as large lobulated masses showing homogeneous attenuation or signal intensity in the anterior mediastinum (Fig. 29-55). Cysts or areas of necrosis may also be seen in association with mediastinal seminoma (see Fig. 29-45). Invasion of adjacent structures is uncommon and calcification is rare. Metastases to regional nodes may occur.

Nonseminomatous Germ Cell Malignancies

The nonseminomatous germ cell tumors of the mediastinum include embryonal cell carcinoma, endodermal sinus tumor, choriocarcinoma, and mixed germ cell tumors.^{133, 148, 175} Teratoma with embryonal cell carcinoma (teratocarcinoma) is the next most common subtype, with pure endodermal sinus tumor, choriocarcinoma, and embryonal carcinoma being much less common. Most patients with malignant nonseminomatous germ cell tumors are symptomatic at presentation, with chest pain, cough, dyspnea, weight loss, and fever. Up to 80% of affected patients have elevated levels of AFP and 54% have elevated levels of β -hCG. An association exists between malignant nonseminomatous germ cell tumors of the mediastinum and hematologic malignancies. Up to 20% of affected patients have Klinefelter's syndrome.

On CT or MRI, these tumors manifest as large, poorly margined masses showing heterogeneous attenuation or signal intensity (Figs. 29-56 and 29-57). Invasion of the adjacent mediastinal structures, chest wall, and lung, as

Figure 29-55. Seminoma. Contrast-enhanced CT shows anterior mediastinal mass (M) with a central area of low attenuation consistent with necrosis.

Figure 29-56. Malignant teratoma. Contrast-enhanced CT shows a large anterior mediastinal mass. The mass is heterogeneous in attenuation with components of soft tissue, fluid, calcium, and fat (arrows). The mediastinal invasion is diffuse. A, aorta; P, pulmonary artery.

well as metastases to the regional lymph nodes and distant sites, is common.

Parathyroid Adenoma

Because neck exploration for parathyroid gland removal is curative in over 90% of patients with primary hyperparathyroidism, surgeons often do not obtain preoperative imaging studies to localize the parathyroid glands; however, 10% of parathyroid adenomas are ectopic in location and the majority of ectopic adenomas are located either in the region of the tracheoesophageal groove or in the anterior mediastinum.* Such ectopic adenomas can be missed at surgical exploration. Preoperative localization of ectopic parathyroid adenomas can reduce operative time, postoper-

*See References 1, 8, 114–116, 120, 127, 135, 145, 146, 189, 221, 239, and 241.

Figure 29-57. Nonseminomatous germ cell malignancy. CT shows large mixed-attenuation anterior mediastinal mass. Trans-thoracic needle aspiration biopsy revealed endodermal sinus tumor. The left pectoralis major muscle is absent, consistent with Poland syndrome. A, aorta; S, superior vena cava.

Figure 29-58. Ectopic parathyroid adenoma. CT shows a soft tissue mass in a patient who had undergone neck dissection for hyperparathyroidism with persistently elevated serum calcium. The parathyroid gland (P) is ectopic, located posterior to manubrium.

ative morbidity, and the need for a subsequent surgical procedure.

Imaging techniques for localizing abnormal parathyroid glands include sonography, radionuclide imaging (technetium-99m-sestamibi [^{99m}Tc -MIBI], ^{99m}Tc -tetrofosmin), CT, and MRI. On CT, ectopic mediastinal parathyroid glands manifest as 1- to 2-cm rounded masses that may resemble lymph nodes (Fig. 29-58). CT or MRI can detect these glands, but careful evaluation is required so that small lesions are not overlooked.

MRI is accurate in identifying abnormal parathyroid glands in ectopic locations. Functioning parathyroid adenomas show intermediate signal intensity on T1-weighted images and usually show marked increased signal intensity on T2-weighted images (Fig. 29-59). Similar findings are seen in cases of parathyroid hyperplasia and carcinoma. Up to 13% of abnormal glands, however, do not show high signal intensity on T2-weighted images because of fibrosis or hemorrhage. Although MR is comparable or superior to other imaging modalities for detecting parathyroid disease (sensitivity, 78%; specificity, 90%; accuracy, 90%), the most appropriate role of MRI is as an adjunct to ^{99m}Tc -MIBI radionuclide imaging. In this setting MRI provides accurate anatomic location of the adenoma and can be useful in predicting the need for mediastinotomy or lateral cervical incision.

Although the precise role of imaging in the evaluation of a virgin neck for hyperparathyroidism may be debated, imaging is useful in second-look procedures and in those patients considered to be at high risk for surgery. In this population, the success rate for surgery is reduced, ranging from 64% to 90%, and the combined use of ^{99m}Tc -MIBI and MRI has been shown to be 89% sensitive and 95% specific for preoperative localization.

Lymphatic Malformations

Lymphatic malformations (previously called lymphangiomas) are rare benign lesions that comprise 0.7% to 4.5% of all mediastinal tumors.^{123, 185, 197, 225, 230, 233, 268} Approxi-

Figure 29-59. Ectopic parathyroid adenoma in a woman with persistent hyperparathyroidism after surgical neck exploration. MR images show 1-cm mass (arrowheads) in anterior mediastinum with intermediate signal intensity (similar to muscle) on T1-weighted image (A) and high signal intensity on T2-weighted image (B). MR appearance is typical of parathyroid adenoma. T, trachea; V, vertebral body. (Reprinted with permission from Erasmus JJ, McAdams HP, Donnelly LF, Spritzer CE: MR imaging of mediastinal masses. *Magn Reson Imaging Clin North Am* 8:59-89, 2000.)

mately 75% occur in the neck, 20% in the axillary region, and 5% in the mediastinum. Primary mediastinal lymphatic malformations are rare and most mediastinal lesions are the result of tumor extension from the neck. Lymphatic malformations are usually located in the superior and anterior mediastinum, although they can occur in any mediastinal compartment. They usually occur in patients less than 2 years old and there is a male predominance. In adults, lymphatic malformations are usually located in the mediastinum and are often the result of recurrence of an incompletely resected childhood tumor.

On CT, these lesions manifest as lobular, multicystic tumors that surround and infiltrate adjacent mediastinal structures (Fig. 29-60). They can appear solid on CT because of protein or hemorrhage within the cysts. The cysts are typically 1 to 2 cm in diameter, and the septa may enhance following administration of IV contrast material.

MRI can be useful in confirming the cystic nature of these lesions; lymphatic malformations usually show markedly increased signal intensity on T2-weighted images. Their appearance on T1-weighted sequences is more variable, although most show low to intermediate signal intensity (similar to skeletal muscle) and can contain focal areas of signal intensity higher than that of muscle. Occasionally, lymphatic malformations show high signal intensity similar to that of fat on T1-weighted images.

Because surgical resection is the treatment of choice, multiplanar MRI can be useful in preoperative evaluation of local invasion and determination of anatomic extent of tumor.

Hemangiomas

Hemangiomas are rare mediastinal tumors that account for less than 0.5% of all mediastinal masses.^{117, 121, 163, 223, 224}

Figure 29-60. Lymphangioma. A, Contrast-enhanced CT shows homogeneous, water-attenuation mass (arrows) in superior mediastinum, which arose in the neck. S, superior vena cava; T, trachea. B, The mass diffusely infiltrates mediastinum and extends into the right hilum.

Figure 29-61. Hemangioma. A, Non-contrast-enhanced CT shows small homogeneous anterior mediastinal mass (arrowheads). B, Contrast-enhanced CT shows marked enhancement, typical of hemangioma (arrowheads). A, ascending aorta.

Mediastinal hemangiomas usually occur in the anterior (68%) or posterior mediastinum (22%), although multicompartiment involvement occurs in up to 14% of cases. Most mediastinal lesions are cavernous hemangiomas and are composed of large interconnecting vascular spaces with varying amounts of interposed stromal elements such as fat and fibrous tissue. Focal areas of organized thrombus can calcify as phleboliths.

On radiographs, hemangiomas manifest as sharp, smoothly margined mediastinal masses. Phleboliths are seen in less than 10% of cases. CT typically reveals a heterogeneous mass with intense central or peripheral rim-like enhancement after administration of IV contrast material (Fig. 29-61). Hemangiomas typically show heterogeneous signal intensity on T1-weighted images. In lesions with significant stromal fat, linear areas of increased signal intensity on T1-weighted images can occasionally be identified. The central vascular lakes typically become markedly hyperintense on T2-weighted images, a suggestive feature (Fig. 29-62).

Middle Mediastinal Abnormalities

Lesions that occur primarily in the middle mediastinum include esophageal lesions, airway lesions, foregut duplication cysts, and pericardial cysts.

Esophagus

Esophageal Cancer

CT is used to help stage esophageal carcinoma by demonstrating the following (Fig. 29-63):*

- Thickness of the esophageal wall
- Length of the lesion
- Involvement of adjacent structures such as airway, aorta, pericardium, and spine
- Nodal spread to regional mediastinal, celiac, and gastrohepatic ligament nodes

Endoscopy, endoscopic ultrasound, and esophagography are also helpful in staging esophageal carcinoma. Invasion of local structures is common because the esophagus lacks a serosa. CT and MRI can both overestimate or underestimate the degree of local invasion because the lack of normal fat planes between the esophagus and adjacent structures makes invasion difficult to determine.

Anterior displacement of the carina or left main bronchus suggests airway invasion; contact with the aorta that exceeds one quarter of the aortic circumference suggests the possibility of aortic invasion. All imaging findings must be interpreted in conjunction with the patient's clinical status when planning treatment. CT is also useful in planning radiation treatment ports and for imaging complications resulting from esophagectomy.

The normal esophagus is not optimally demonstrated on MRI because of peristaltic motion and relatively poor spatial resolution. Distinguishing small mucosal tumors from normal esophagus is difficult because both show intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images. The role of MRI for intrathoracic staging of esophageal neoplasms is limited. Although some authors have reported high intrathoracic staging accuracy for MRI, most reports suggest that MRI is no better than CT in this regard. MRI can be useful as a problem-solving modality, however, when invasion of pericardium or heart is suspected on CT or if the patient is allergic to iodinated contrast material.

*See References 73, 93, 109, 144, 147, 153, 179, 196, 202, 207, and 248.

Figure 29-62. Hemangioma. A, CT shows heterogeneous mass (arrowheads) in anterior mediastinum. Punctate calcification is consistent with phlebolith within mass (arrow). B, Coronal T1-weighted MR image shows mass of intermediate signal intensity (arrowheads) in anterior and superior mediastinum. Septa within the mass and invasion of mediastinum can be seen. C, Axial T2-weighted MR image shows high signal intensity within the mass (arrowheads). The MRI appearance is typical for hemangioma. b, brachiocephalic artery; H, heart, T, trachea. The asterisk indicates the carotid artery.

Figure 29-63. Esophageal malignancy. A, Contrast-enhanced CT shows a large, barium-filled hiatal hernia containing a polypoid mass (arrowheads). B, The more cephalic image shows a large heterogeneous esophageal mass. An adjacent lymph node is consistent with metastasis (arrow). C, A more cephalic image shows dilation of the esophagus and an air-fluid level (arrows). A metastatic left rib lesion can be seen (arrowheads). T, trachea.

Esophageal Dilatation

Esophageal dilatation can be easily demonstrated on CT.^{52, 203} Focal dilatation occurs in Zenker's diverticulum (upper esophagus), traction diverticula resulting from granulomatous disease (middle esophagus), and epiphrenic diverticula (lower and on the right). These focal dilatations or diverticula are clearly demonstrated on CT and can be a source of confusion unless oral contrast material is administered.

Diffuse dilatation of the esophagus can occur as a result of motility disorders (achalasia, postvagotomy syndrome, Chagas' disease, scleroderma, systemic lupus erythematosus, presbyesophagus, diabetic neuropathy, esophagitis) or as a result of distal obstruction (carcinoma, stricture, extrinsic compression) (Fig. 29–64).

Airway Lesions

Tumors of the trachea or proximal bronchi can manifest as middle mediastinal masses on chest radiographs or CT.^{41, 138, 164} Malignant neoplasms account for 90% of primary tracheal tumors. The most common primary malignancies of the trachea are squamous cell and adenoid cystic carcinomas.^{11, 158, 159, 194} Benign neoplasms such as papilloma, adenoma, hamartoma, chondroma, leiomyoma, and granular cell myoblastoma account for less than 10% of primary tracheal tumors. The most common primary malignancy of the major bronchi is non-small cell lung cancer. Carcinoid tumors and mucoepidermoid carcinoma are less common bronchial malignancies that occur in younger patients.^{129, 166, 211} These lesions are described in Chapter 28.

Foregut Cysts

Foregut cysts, which account for approximately 20% of all mediastinal masses, probably arise as a result of maldevelopment of the primitive foregut.^{234, 235} Bronchogenic cysts are the most common mediastinal foregut cysts; esophageal duplication and neurenteric cysts are less common.

It is important not to confuse these cystic masses with fluid-filled structures within the mediastinum such as fluid-

Figure 29–64. Achalasia. CT shows dilated esophagus (A) in a patient with achalasia. The esophagus displaces the azygos vein to the right.

Figure 29–65. Thoracic lymphocele after esophageal resection and gastric pull-through. Contrast-enhanced CT shows large homogeneous fluid collection (arrowheads) in middle/posterior mediastinum displacing tracheal carina (asterisks) anteriorly and gastric pull-through anterolaterally. A, ascending aorta; D, descending aorta.

filled pericardial recesses, loculated pleural fluid, extension of ascites through the esophageal hiatus, mediastinal extension of pancreatic pseudocyst, or a fluid-filled and dilated esophagus (Figs. 29–65 and 29–66).

Bronchogenic Cyst

Bronchogenic cysts are thought to arise from abnormal budding of the ventral foregut.* Histopathologically, they are lined with ciliated respiratory epithelium, cartilage, smooth muscle, fibrous tissue, and mucous glands. Most bronchogenic cysts occur in the middle mediastinum, typically in the subcarinal or right paratracheal region. In up to 15% of cases, bronchogenic cysts are found in unusual locations including the pleural space, diaphragm, pericardium, lung, and abdomen.

On CT, bronchogenic cysts typically manifest as round or spherical, sharply margined, homogeneous masses. Approximately half of bronchogenic cysts show water attenuation on CT (Fig. 29–67). The remainder show increased attenuation, most likely secondary to proteinaceous debris or hemorrhage within the lesions (Fig. 29–68). A small percentage have calcified walls or contain calcium suspended within the fluid.

On MR images, lesions typically show low to intermediate signal intensity on T1-weighted images and markedly increased signal intensity on T2-weighted images. The lesions can be heterogeneous on T1-weighted images but are typically homogeneous on T2-weighted images. These MRI characteristics can be useful for differentiating cysts that appear solid on CT from solid neoplasms or lymphadenopathy. Gadolinium administration can also be helpful for distinguishing mediastinal cysts from solid neoplasms by demonstrating a lack of central enhancement and, occasionally, rim enhancement.

Because many ECG-gated T1-weighted pulse sequences have a relatively long TR, fluid-filled lesions can show

*See References 14, 47, 122, 141, 153, 154, 156, 162, 180, 184, and 245.

Figure 29-66. Mediastinal pseudocyst in a patient with chronic pancreatitis. **A**, Contrast-enhanced CT shows homogeneous water-attenuation mass (**C**) in the middle mediastinum with a thin enhancing rim (**arrowheads**). A small left pleural effusion can be seen. **A**, aorta; **H**, heart. **B**, A more caudal CT image confirms origination of mass (**arrowheads**) from the tail of the pancreas. (Case is courtesy of May Lesar, Bethesda, Md.)

Figure 29-67. Bronchogenic cyst. Contrast-enhanced CT shows well-circumscribed, water-attenuation middle mediastinal mass (**arrow**) with imperceptible wall. The CT appearance is typical for bronchogenic cyst. **A**, transverse aorta; **S**, superior vena cava; **T**, trachea.

Figure 29-68. Bronchogenic cyst. **A**, CT shows a large homogeneous mass (**M**) of soft tissue attenuation in subcarinal region. **B**, Coronal T1-weighted MR image shows high signal intensity within the mass (**BC**), caused by viscous cyst fluid.

Figure 29-69. Bronchogenic cyst. Coronal T1-weighted MRI shows a subcarinal mass with high signal intensity. Both main bronchi are displaced. The subcarinal location is typical for a bronchogenic cyst. T, trachea.

intermediate signal intensity. Cysts with proteinaceous, mucinous, or hemorrhagic contents can show a further increase in signal intensity on these sequences (Fig. 29-69). These lesions usually have markedly increased signal intensity on T2-weighted images, however, suggesting their true cystic nature.

Esophageal Duplication and Neurenteric Cysts

Duplication of the esophagus^{66, 130, 141, 180, 234, 245} is thought to represent a diverticulum of the primitive foregut or an aberrant recanalization of the gut in embryogenesis. These cysts are located in the middle or posterior mediastinum and may be indistinguishable from a bronchogenic cyst. They are composed of a muscular coat and mucosa that may resemble the esophagus, stomach, or small intestine, although it is usually ciliated. Esophageal duplication cysts usually occur within the wall, or are adherent to the wall, of the esophagus. They are either spherical or tubular and are usually located distally along the lateral aspect of the esophagus.

On CT, the cysts typically manifest as spherical or tubular masses in close proximity to the esophageal wall. They are usually homogeneous and demonstrate water attenuation (Fig. 29-70). Like bronchogenic cysts, however, they may be of soft tissue attenuation because of intracystic hemorrhage or proteinaceous debris. On MRI, they show signal intensity characteristics similar to those of bronchogenic cysts, with variable signal intensity on T1-weighted images, depending on intracystic content, and markedly increased signal intensity on T2-weighted images (Fig. 29-71).

Neurenteric cysts result from incomplete separation of the endoderm and notochord, resulting in a diverticulum of the endoderm. Neurenteric cysts, which are pathologically identical to esophageal duplication cysts, may have either a fibrous connection to the spine or an intraspinal component. These cysts are typically associated with vertebral body

Figure 29-70. Esophageal duplication cyst. Contrast-enhanced CT shows a well-marginated, low-attenuation middle mediastinal mass (arrow) adjacent to the left lateral wall of the esophagus (asterisk). Note the lack of enhancement. A, aorta.

anomalies, most commonly a sagittal cleft, that occur at or above the level of the cyst. Most neurenteric cysts occur in the posterior rather than the middle mediastinum, usually above the level of the carina.

The CT and MR appearances of these lesions are similar to those of other foregut cysts. MRI is useful for optimally demonstrating extent of spinal abnormality and degree of intraspinal involvement.

Pericardial Cysts

Pericardial cysts are unilocular, mesothelium-lined cysts that arise from congenital defects related to the ventral and parietal pericardial recesses.^{15, 63, 180, 219, 245} True pericardial cysts contain all layers of the pericardium and do not

Figure 29-71. Esophageal duplication cyst. Axial T1-weighted MR image shows a well-circumscribed mass (arrow) with high signal intensity adjacent to the descending aorta (A). The MRI appearance, which is atypical for a simple cyst, is caused by proteinaceous fluid within the cyst.

Figure 29–72. Pericardial cyst. Contrast-enhanced CT shows a large, homogeneous, water-attenuation mass (C) in the right cardiophrenic angle. The wall is imperceptible; enhancement at the periphery (arrows) is caused by atelectatic lung. The location and appearance are typical for pericardial cyst.

communicate with the pericardial space. They are usually found in asymptomatic adults, often as an incidental finding on chest radiographs. They are typically unilocular cystic lesions with clear fluid contents and thin walls. Pericardial cysts are variable in size and shape and most commonly occur in the right (70%) or left (22%) cardiophrenic angles.

CT shows a homogeneous, nonenhancing, water-attenuation, rounded mass adjacent to the pericardium (Fig. 29–72). The cyst wall may calcify. Pericardial cysts are usually homogeneous on MRI, showing low signal intensity on T1-weighted images and markedly increased signal intensity on T2-weighted images (Fig. 29–73).

Posterior Mediastinal Lesions

Neurogenic Tumors

Twenty percent of all adult and 35% of all pediatric mediastinal neoplasms are neurogenic tumors.^{12, 47, 153, 245, 265} Neurogenic tumors account for the majority of posterior mediastinal neoplasms.¹²⁴ These lesions can be classified as tumors of peripheral nerves (neurofibromas, schwannomas, malignant tumors of nerve sheath origin), of sympathetic ganglia (ganglioneuromas, ganglioneuroblastomas, neuroblastomas), or of parasympathetic ganglia (paragangliomas, pheochromocytomas). Peripheral nerve tumors are more common in adults and sympathetic ganglia tumors are more common in children.

CT is usually performed in the initial evaluation of a suspected neurogenic tumor and is helpful for identifying intratumoral calcification and for assessing associated bone erosion or destruction. Because neurogenic tumors usually arise in a paravertebral location, intraspinal extension is common.

MRI is the preferred imaging modality for evaluating neurogenic tumors because it allows simultaneous assessment of the following:

- Intraspinal extension
- Spinal cord abnormalities
- Longitudinal extent of tumor

Although the various types of neurogenic tumor can have similar radiologic appearances, certain features aid in the diagnosis. Peripheral nerve tumors typically manifest in adults as round masses oriented along the axis of a peripheral nerve, and they may have an intraspinal component (the “dumbbell” lesion). Tumors of sympathetic ganglia typically manifest in children as oval masses that are elongated along the spine and may contain calcifications on CT.

Benign Peripheral Nerve Tumors

The benign peripheral nerve tumors (schwannomas, neurofibromas) are slow-growing neoplasms and the most common neurogenic tumors of the mediastinum.* Schwannomas are encapsulated neoplasms that arise from the nerve sheath and typically have areas of cystic degeneration and hemorrhage and small focal areas of calcification. Schwannomas grow laterally along the parent nerve and cause symptoms by compressing the nerve.

Neurofibromas differ from schwannomas in that they are unencapsulated and result from proliferation of all nerve elements, including Schwann cells, nerve fibers, and fibroblasts. They grow by diffusely expanding the parent nerve. This type of neural tumor is found in neurofibromatosis-1 (von Recklinghausen’s disease). Plexiform neurofibromas are variants of neurofibromas that infiltrate along nerve trunks or plexuses.

Schwannomas and neurofibromas typically occur with equal frequency in men and women, most commonly in the third and fourth decades of life. Thirty percent to 45% of neurofibromas occur in patients with neurofibromatosis. Multiple neurogenic tumors or a single plexiform neurofibroma is pathognomonic of the disease.

On CT, schwannomas and neurofibromas manifest as sharply margined, unilateral, spherical or lobular posterior mediastinal masses (Fig. 29–74). Pressure erosion of adjacent ribs, or vertebral body or neural foramen enlargement occurs in up to 50% of cases. Punctate intralesional calcification occurs occasionally. On non-contrast-enhanced CT, schwannomas often demonstrate lower attenuation than skeletal muscle because of their high lipid content, interstitial fluid, and areas of cystic degeneration. Neurofibromas are often more homogeneous and show higher attenuation than schwannomas because they have fewer of these histologic features. These lesions may heterogeneously enhance following administration of IV contrast material.

On MRI, schwannomas and neurofibromas show variable signal intensity on T1-weighted images but typically their signal intensity is similar to that of the spinal cord. On T2-weighted images, these neoplasms characteristically show high signal intensity peripherally and low signal intensity centrally (the target sign) as a result of collagen deposition. This feature, when present, helps distinguish neurofibromas from other mediastinal tumors. Also, areas

*See References 9, 26, 36, 74, 95, 136, 153, 155, 206, 245, 247, and 265.

Figure 29-73. Pericardial cyst. CT (A) shows small, low-attenuation, well-circumscribed mass in the right cardiophrenic angle (arrow). MRI shows that the mass (arrow in B) is homogeneous with low signal intensity on the T1-weighted image (B) and with high signal intensity on the T2-weighted image (C). The MRI appearance is typical of a pericardial cyst.

of cystic degeneration within the lesions may result in foci of increased signal intensity on T2-weighted images.

Although the high signal intensity shown by schwannomas and neurofibromas on T2-weighted images can facilitate differentiation of tumors from spinal cord, the tumors can be obscured by the high signal intensity of cerebrospinal

fluid. Schwannomas and neurofibromas, however, enhance with gadolinium and this feature can be useful in detecting and determining their intradural extension (Fig. 29-75). Ten percent of paravertebral neurofibromas and schwannomas extend into the spinal canal and appear as dumbbell-shaped masses with widening of the affected neural foramen.

CT of plexiform neurofibromas demonstrates low-attenuation infiltrative masses along the mediastinal nerves and sympathetic chains, which may occur in any mediastinal compartment. MRI of plexiform neurofibromatosis also demonstrates the infiltrative nature of the tumors, and the masses can show low signal on both T1-weighted and T2-weighted images because of the fibrous nature of the tumors (Fig. 29-76).

Malignant Tumor of Nerve Sheath Origin

Malignant tumors of nerve sheath origin (also called malignant neurofibromas, malignant schwannomas, or neurofibrosarcomas) are rare neoplasms that typically develop from solitary or plexiform neurofibromas in the third to fifth decades of life.* Up to 50% occur in patients with neurofibromatosis-1. In patients with neurofibromatosis-1, these tumors occur at an earlier age (typically in adolescence) and with a higher incidence than in the general population. Because most benign neurogenic tumors are

Figure 29-74. Schwannoma. CT shows a large, homogeneous, paraspinal mass. The round shape is typical of a peripheral nerve tumor. A, aorta; P, pulmonary artery. The asterisk indicates the right main bronchus.

*See References 9, 26, 55, 80, 110, 136, 155, 157, 245, and 247.

Figure 29-75. Neurofibroma. A, Coronal T1-weighted MR image shows a lobular mass extending into the intervertebral foramina (arrowheads). B, Coronal gadolinium-enhanced MR image shows heterogeneous enhancement within the mass (arrowheads). V, vertebral body. (From Rossi SE, Erasmus JJ, McAdams HP, Donnelly LF: Thoracic manifestations of neurofibromatosis-I. *AJR Am J Roentgenol* 173:1631–1638, 1999.)

asymptomatic, the development of pain often indicates malignant transformation.

On CT or MRI, malignant tumors of nerve sheath origin typically manifest as posterior mediastinal masses larger than 5 cm in diameter. Although benign and malignant neurogenic tumors cannot be differentiated with certainty, findings that suggest malignancy include a sudden change in size of a preexisting mass or development of heterogeneous signal intensity on MR images (caused by necrosis and hemorrhage). The presence of multiple target signs throughout the lesion on MRI favors the diagnosis of a plexiform neurofibroma rather than a malignant tumor of nerve sheath origin.

Sympathetic Ganglia Tumors

The sympathetic ganglia tumors (ganglioneuromas, ganglioneuroblastomas, neuroblastomas) are rare neoplasms that originate from nerve cells.* Ganglioneuromas and ganglioneuroblastomas usually arise from the sympathetic ganglia in the posterior mediastinum.

Ganglioneuromas are benign neoplasms that usually occur in children and young adults. Ganglioneuroblastomas, which exhibit varying degrees of malignancy, usually occur in patients younger than 10 years. The posterior mediasti-

*See References 2, 19, 40, 48, 74, 218, 229, 240, 245, 247, and 255.

Figure 29-76. Plexiform neurofibromas in a woman with neurofibromatosis. Coronal T1-weighted (A) and T2-weighted (B) MR images show plexiform neurofibromas along the course of nerves in the superior, middle, and posterior mediastinum (arrowheads). Focal central hypointense regions within masses (target sign) are typical of neurofibromas. (From Rossi SE, Erasmus JJ, McAdams HP, Donnelly LF: Thoracic manifestations of neurofibromatosis-I. *AJR Am J Roentgenol* 173:1631–1638, 1999.)

num is also the most common extra-abdominal location of neuroblastomas: up to 30% of these tumors occur in this region. Neuroblastomas are highly malignant tumors that typically occur in children younger than 5 years. A posterior mediastinal mass in this age group should be considered a neuroblastoma until proven otherwise.

Radiologically, ganglioneuromas and ganglioneuroblastomas usually manifest as well-marginated, elliptical, posterior mediastinal masses that vertically extend over three to five vertebral bodies. They are usually located lateral to the spine and may cause pressure erosion on adjacent vertebral bodies. On CT, they are typically heterogeneous and may contain stippled or punctate calcifications (Fig. 29-77). On T1-weighted and T2-weighted MR images, they usually show homogeneous and intermediate signal intensity (Fig. 29-78). Occasionally, these lesions show heterogeneous and high signal intensity on T2-weighted images. Ganglioneuroblastomas are typically larger and more aggressive than ganglioneuromas, with evidence of local and intraspinal invasion.

On CT, neuroblastomas manifest as a paraspinal mass showing heterogeneous, predominantly soft tissue attenuation. The lesions usually contain areas of hemorrhage, necrosis, cystic degeneration, and calcium (30%). On MRI, the lesions typically demonstrate heterogeneous signal intensity on all pulse sequences and show heterogeneous enhancement following gadolinium administration. Neuroblastomas often show widespread local invasion and have irregular margins, although lesions can be well marginated on CT or MR images. Neuroblastomas also have a tendency to cross the midline.

Parasympathetic Ganglion Tumors

Paragangliomas (chemodectomas) are rare neural tumors of the extra-adrenal parasympathetic system.^{71, 174} These tumors are histologically identical to pheochromocytomas and can be functional or nonfunctional. Mediastinal paragangliomas occur in one of two locations:

- In the middle mediastinum, in close association with the origins of the aorta and pulmonary artery (aorticopulmonary paraganglioma)

Figure 29-77. Ganglioneuroma. Contrast-enhanced CT shows well-circumscribed low-attenuation paraspinal mass containing punctate calcification (arrows). LA, left atrium.

Figure 29-78. Ganglioneuroma. Coronal T1-weighted MR image shows an elliptical paraspinal mass (arrowheads) of intermediate signal intensity. Vertical orientation and signal characteristics are typical of a sympathetic ganglion tumor. L, liver; S, spleen.

- In the posterior mediastinum (paravertebral paraganglioma)

On non-contrast-enhanced CT, the lesions are typically heterogeneous and enhance intensely after administration of IV contrast material. On MRI, the lesions are usually hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 29-79). Flow voids in the lesion are sometimes seen, indicating their hypervascular nature. The lesions may be well circumscribed or show invasion of surrounding mediastinal structures.

Lateral Thoracic Meningocele

Because of the pressure difference between the thorax and the subarachnoid space, pulsion diverticula, called lateral meningoceles, can develop and protrude through the adjacent neural foramina.^{9, 113, 183, 205, 236} They occur most commonly in patients with neurofibromatosis-1. Lateral meningoceles manifest radiographically as well-circumscribed, paravertebral masses that usually occur on the convex side of a scoliosis. On CT, meningoceles manifest as well-circumscribed paraspinal masses that demonstrate water attenuation. The adjacent neural foramen is typically enlarged. These lesions can be confused with low-attenuation neurofibromas. Diagnosis is established by demonstration of communication with the subarachnoid space by CT myelography. MRI can also be helpful in differentiating meningoceles from neurofibromas because meningoceles typically show low signal intensity on T1-weighted images and high signal intensity on T2-weighted images, and they do not enhance after gadolinium administration. Cardiac-gated MR cine images of meningoceles can reveal pulsatile motion that results from communication with the subarachnoid space.

Figure 29-79. Paraganglioma. A, CT shows homogeneous soft tissue mass in aortopulmonary window (arrowheads). The mass is difficult to distinguish from the aorta. A, ascending aorta; D, descending aorta. B, Coronal T1-weighted MR image shows intermediate-signal-intensity aortopulmonary window mass (arrowheads). Biopsy revealed paraganglioma. A, aorta; T, trachea.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis is a compensatory phenomenon that occurs when erythrocyte production is diminished or destruction is accelerated.^{30, 81, 90, 123, 222} Extramedullary hematopoiesis is usually seen in patients with chronic hemolytic disorders such as thalassemia, hereditary spherocytosis, sickle cell disease, or extensive bone marrow replacement resulting from myelofibrosis. Extramedullary hematopoiesis usually is microscopic and commonly involves the liver, spleen, and lymph nodes. Thoracic manifestations are less common and consist of paravertebral soft tissue masses. The masses represent extrusion of the marrow through the thinned cortex of the posterior ribs. Histologically, the masses resemble splenic tissue with hematopoietic elements mixed with fat. They are usually bilateral, contain no calcification, and show no rib destruction. Additional masses can be found along the lateral margins of the ribs.

On CT, extramedullary hematopoiesis manifests as a heterogeneous mass or masses, often with focal areas of fat within the lesion (Fig. 29-80). Extramedullary hematopoiesis typically manifests on MRI as well-marginated, smooth or lobulated, unilateral or bilateral paravertebral masses. T1-weighted and T2-weighted MR images typically show bilateral heterogeneous masses with increased signal intensity on T1-weighted images because of fat within the masses.

Paraspinal Inflammation

Vertebral osteomyelitis can result in a paraspinal abscess. Causative organisms include *Mycobacterium tuberculosis*, *Staphylococcus aureus*, and anaerobic organisms. On CT, a paraspinal abscess manifests as a mass showing heterogeneous attenuation. Rim enhancement following administration of IV contrast material is characteristic (Fig. 29-81). Imaging features that suggest paraspinal abscess include (1) narrowing of adjacent intervertebral disk and (2) destruction of two or more contiguous vertebral bodies.

MRI is especially suited for identifying and demonstrating the extent of paraspinal infections. Spondylitis and

vertebral osteomyelitis are often accompanied by epidural or paraspinal inflammatory masses or abscesses. MRI is better than CT for evaluating these infections because of its ability to depict the disk space, the spinal canal and its contents, and the paraspinal regions. T1-weighted images show inflammation as low signal intensity, and T2-weighted images show high signal intensity. The addition of gadolinium diethylenetriamine-penta-acetic acid (Gd-DTPA) is helpful in demonstrating the extent of the inflammatory process.^{4, 5, 45, 191}

Diffuse Mediastinal Abnormalities

Numerous lesions, including lymphadenopathy, mediastinitis, mediastinal sarcoma, and metastatic disease, can

Figure 29-80. Extramedullary hematopoiesis. CT shows well-circumscribed bilateral paravertebral masses (arrowheads). The left mass is heterogeneous and contains focal areas of fat, typical for extramedullary hematopoiesis. A, descending aorta.

Figure 29-81. Paraspinal abscess caused by vertebral osteomyelitis. Contrast-enhanced CT shows bilateral heterogeneous low-attenuation paraspinal masses (arrowheads). *Staphylococcus aureus* was cultured from the needle aspirate. An anomalous right subclavian artery (asterisk) is posterior to the trachea (T).

manifest as diffuse or multicompartiment mediastinal disease.

Lymphadenopathy

Lymph nodes are common in all regions of the mediastinum but they are most numerous around the tracheobronchial tree and hence in the middle mediastinum (Fig. 29-

82).^{*} Although it is still a subject of some controversy, the generally accepted upper limit of normal for short-axis lymph node diameter is 1 cm.

Enlargement is the primary CT or MRI criterion for establishing the presence of lymph node disease, but attenuation is also important. For instance, diffuse calcification is typical of prior granulomatous infection (tuberculosis, histoplasmosis), sarcoidosis, silicosis, calcifying or ossifying metastases, and treated lymphoma (Figs. 29-83 and 29-84). Nodes with low attenuation centers and rim enhancement are often seen in patients with active infection, (tuberculosis, nontuberculous mycobacterial disease) and in patients with metastatic disease to the lymph nodes (lung cancer, testicular germ cell malignancy). Diffuse, intense nodal enhancement after administration of IV contrast material is typical of Castleman's disease and some metastatic processes (renal cell carcinoma). Causes of mediastinal lymph node enlargement may be classified as follows:

- Primary neoplasms of lymph nodes (lymphoma, leukemia)
- Metastases from intrathoracic or extrathoracic primary malignancies
- Nonlymphomatous lymphoid disorders such as Castleman's disease
- Infection (e.g., tuberculosis, fungal infection)

^{*}See References 21, 29, 53, 75, 77, 85, 153, 193, 198, and 257.

Figure 29-82. Diffuse mediastinal adenopathy in a patient with chronic lymphocytic leukemia. Contrast-enhanced CT shows marked intrathoracic adenopathy in the paratracheal and prevascular mediastinum (A), precarinal region and aortopulmonary window (B), left and right hilum (C), and subcarinal region (D). Axillary adenopathy can be seen (arrowheads in A). A, ascending aorta; B, brachiocephalic vein; D, descending aorta; P, main pulmonary artery; S, superior vena cava; T, trachea; TA, transverse aorta.

Figure 29-83. Osteosarcoma metastasis to the anterior mediastinum. Contrast-enhanced CT shows a soft-tissue-attenuation mass with extensive osteoid (arrowheads) in the anterior mediastinum. A, aorta; P, pulmonary artery.

CT and MRI are generally considered to be equivalent in their ability to detect mediastinal lymph node enlargement (Fig. 29-85). MRI is limited in its ability to detect calcification within nodes, a finding useful for distinguishing benign from malignant lymphadenopathy. Overlap occurs in signal intensity characteristics of benign and malignant lymphadenopathy on both T1-weighted and T2-weighted images. Thus, CT remains the primary modality for diagnosis and characterization of mediastinal lymphadenopathy. MRI can be useful, however, as a problem-solving modality in some cases and for distinguishing enlarged nodes from vascular structures when administration of iodinated contrast material is contraindicated.

Lymphoma

Lymphomas are common mediastinal neoplasms that can be either focal or diffuse.^{67, 96, 125, 140, 151, 226, 242} Lymphomas are classified as *Hodgkin's disease* (HD) and *non-Hodgkin's lymphoma* (NHL). HD is the most common mediastinal lymphoma. Of the four types of HD, nodular sclerosing HD is the most common and has a unique

Figure 29-84. Calcified nodes. CT shows calcified right paratracheal lymph nodes (M) caused by histoplasmosis.

predilection for the anterior mediastinum. Other types of HD typically manifest with diffuse mediastinal lymphadenopathy.

NHL that involves the mediastinum usually manifests with diffuse lymphadenopathy involving anterior, middle, and occasionally posterior mediastinal nodal groups. However, large B-cell or lymphoblastic lymphoma can manifest as an isolated anterior mediastinal mass. These large tumors can obstruct the SVC, compress the airway, or invade chest wall and adjacent structures.

Hodgkin's Disease. HD accounts for 0.75% of all cancers diagnosed in the United States each year. The median age at diagnosis is 26 years, and there is a slight male predominance. The incidence of HD has a bimodal distribution, with peaks between 25 and 30 years and 75 and 80 years. The characteristic Reed-Sternberg cell is the diagnostic hallmark of HD. There are four histologic subtypes of HD:

- Lymphocyte predominance (5%), with the best prognosis
- Nodular sclerosing, the most common type (78%), with the second most favorable prognosis
- Mixed cellularity (17%), with the third most favorable prognosis
- Lymphocyte depletion (1%), with the worst prognosis

HD is staged using the Ann Arbor staging system as follows:

Stage I: Involvement of a single lymph node region

Stage II: Involvement of two or more lymph node regions on the same side of the diaphragm (II), or localized involvement of an extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (IIE)

Stage III: Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by involvement on the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE), or both (IIIES)

Stage IV: Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement

The absence or presence of fever, night sweats, or unexplained weight loss of 10% or more body weight 6 months before diagnosis are denoted by the suffix letter A or B, respectively.

Stages I and II are treated with radiation alone, and stages III and IV are treated with a combination of radiation and chemotherapy or just chemotherapy alone. Survival is greater than 90% in stages I, II, and IIIA; 80% in stage IIIB; and 75% in stage IV.

Non-Hodgkin's Lymphoma. The NHLs are a heterogeneous group of diseases with differing histology, treatment, and prognosis but with enough similarities that they are considered collectively. Although NHL has no known cause, patients with impaired immune systems are at higher risk for development of this malignancy. NHL makes up 3% of all newly diagnosed cancers in the United States and is four times more common than HD. NHL is the third most common childhood cancer, although the median age

Figure 29-85. Metastatic mediastinal adenopathy in a patient with melanoma. Axial T1-weighted images of the chest show lymph nodes of intermediate signal intensity in the high paratracheal (A), low paratracheal (B), and precarinal and aortopulmonary window regions (C) (arrows). A small prevascular lymph node can be seen (black arrow in B). A, aorta; S, superior vena cava; T, trachea.

at the time of diagnosis is 55 years. There is a male predominance (1.4:1). The histologic classification of NHL is complex, with 10 different cell descriptions divided into three grades of tumors:

- *Low grade* (small lymphocytic; follicular with predominantly small cleaved cells; and follicular with mixed small and large cells)
- *Intermediate grade* (follicular with predominantly large cells; diffuse with small cleaved cells; diffuse with mixed small and large cells; and diffuse with large cells, cleaved or noncleaved)
- *High grade* (diffuse large cells; immunoblastic, small noncleaved cells; and lymphoblastic)

Treatment is complex and involves radiation for lower-grade and chemotherapy for higher-grade tumors. Survival is 50% to 70% in low-grade NHL, 35% to 45% in intermediate-grade NHL, and 20% to 30% in high-grade NHL. Several unique observations are seen in NHL. Low-grade tumors may spontaneously regress, recur, or transform into higher-grade tumors. The incidence of NHL is higher in patients with severe immunologic compromise, including congenital immune disorders, transplant immunosuppression, and human immunodeficiency virus. NHL in these patients is often more aggressive and involves extranodal sites, such as the central nervous system, lung parenchyma, and gastrointestinal tract.

Imaging of Lymphoma. CT is the method of choice for identifying and staging HD and NHL.* CT provides accurate measurement of initial tumor size and extent, and it provides a means to follow response to therapy (Figs. 29-86 to 29-93). Chest CT alters initial treatment plans in approximately 10% of patients with HD by detecting more extensive disease. The anterior mediastinal, pretracheal, and hilar nodes are the nodes most commonly involved with HD. Paracardiac, subcarinal, superior diaphragmatic, internal mammary, and axillary nodes are less frequently involved. Calcification within nodes is usually a consequence of radiation therapy but occasionally is detected before treatment. Central areas of low density represent areas of necrosis; the presence of necrosis does not appear to alter treatment response or survival.

Lymphadenopathy varies in size and extent and can manifest as a solitary large mass or as discrete nodes within masses of matted nodes. It is important to recognize bulky mediastinal lymphadenopathy, identified when the diameter of the nodal mass is greater than one third of the thoracic diameter, because its presence may alter therapy.

Intrathoracic disease is noted in only 40% to 50% of patients with NHL at presentation, compared with 85% of patients with HD. In NHL, the most common nodal sites of involvement are not those of HD (anterior, superior

*See References 1, 6, 24, 33, 37, 39, 76, 119, 153, 182, 186, 190, 204, 237, 252, and 269.

Figure 29-91. Non-Hodgkin's lymphoma manifesting as multifocal disease. A, CT shows right paravertebral soft tissue mass (arrowhead). Axillary adenopathy can be seen (arrows). B, CT at a more caudal level shows bilateral paravertebral masses (arrowheads). Small pleural effusions can be visualized bilaterally. A, aorta.

Figure 29-92. Non-Hodgkin's lymphoma with intracardiac involvement. Axial T1-weighted MR image shows a mass of heterogeneous signal intensity extending into right atrium (arrowheads). MRI allows assessment of intravascular and intracardiac tumor extension without administration of intravenous contrast material. L, left ventricle; R, right ventricle. (Reprinted with permission from Erasmus JJ, McAdams HP, Donnelly LF, Spritzer CE: MR imaging of mediastinal masses. *Magn Reson Imaging Clin North Am* 8:59-89, 2000.)

mediastinal nodes), but rather other nodal sites, lung parenchyma, pleura, and pericardium.

CT and scintigraphy using gallium 67 (^{67}Ga) are usually the primary staging modalities in patients with suspected mediastinal lymphoma. Although MRI can reveal additional information in as many as 15% of cases, it is more often used for assessing suspected SVC obstruction, vascular invasion, and chest wall or mediastinal invasion. MRI has also been used to monitor and evaluate response to therapy, to differentiate fibrosis from residual tumor, and to detect recurrent lymphoma.

Residual masses are seen in the immediate follow-up period in up to 88% of patients with HD and in up to 40% of patients with NHL. These residual masses typically resolve over 12 to 18 months. The presence of residual mediastinal abnormalities is of concern because lymphoma eventually recurs in half of these patients, usually at the site of the original mass. Differentiating residual fibrotic mass from persistent or recurrent tumor can be difficult by conventional imaging. MRI can be a useful adjunct to ^{67}Ga scintigraphy for this assessment.

Because of its high water content, untreated lymphoma is typically homogeneous with low to intermediate signal intensity on T1-weighted images and increased signal intensity on T2-weighted images. Patients with nodular sclerosing HD occasionally have focal regions of low signal intensity within the mass on pretreatment T2-weighted images because of intralesional fibrosis.

Figure 29-93. Non-Hodgkin's lymphoma. Contrast-enhanced CT (A) shows a large heterogeneous anterior mediastinal mass. T1-weighted image (B) following therapy shows an intermediate-signal-intensity mass that has decreased in size. The corresponding T2-weighted image (C) shows mass to have lower signal intensity than B. The decrease in signal intensity suggests that the residual mass is fibrotic. Biopsy confirmed fibrosis and absence of residual tumor. A, ascending aorta; P, main pulmonary artery; S, superior vena cava.

From an *Imaging of the Chest*, 2nd ed, by J. H. Thrall, MD, and J. H. Thrall, MD. Copyright © 2005 by Elsevier Inc. All rights reserved.

During and immediately after completion of therapy, the lesions typically become heterogeneous on MRI and signal intensity on T2-weighted images becomes more variable. Over the subsequent 4 to 6 months, the residual mass has a tendency to decrease in size and signal intensity on T2-weighted images. Six months after therapy, residual masses resulting from fibrosis should be homogeneous with low signal intensity on both T1-weighted and T2-weighted images. This homogeneous low signal intensity is typical of treated inactive lymphoma. If the mass remains heterogeneous with focal regions of high signal intensity on T2-weighted images, recurrent or residual lymphoma is suggested. Using these findings, MRI can detect persistent or recurrent tumor in treated patients as much as 8 to 12 weeks before the onset of clinical symptoms.

The presence of fat mixed with residual fibrotic tissue is, however, a pitfall on MRI. This potential misinterpretation can be avoided by realizing that regions of high signal intensity detected on T2-weighted images correlate with high signal intensity fat on T1-weighted images (rather than low signal intensity of recurrent tumor). Fat-suppression pulse sequences may also be helpful for distinguishing interspersed fat from areas of residual tumor.

Castleman's Disease

Castleman's disease is also known as **angiofollicular or giant lymph node hyperplasia**.^{126, 134, 161, 165, 171, 195} Castleman's disease is not a distinct disease entity but rather a diverse group of rare lymphoproliferative disorders of different tissue types and biologic behaviors. It is currently classified into two major subgroups: localized and disseminated Castleman's disease. There are two major histologic variants: *hyaline vascular* (HV-CD) and *plasma cell* (PC-CD). Although Castleman's disease most often affects the mediastinum, it can occur in any location (mediastinum, 67%; neck, 14%; pelvis, 4%; axilla, 2%).

Localized Castleman's Disease. Most patients with localized thoracic Castleman's disease have HV-CD; localized PC-CD is rare. Localized HV-CD affects all age groups, with a peak incidence in the fourth decade of life. Affected patients are usually asymptomatic at presentation, although symptoms caused by compression or invasion of

adjacent structures occur occasionally. Women are more commonly affected than men. Systemic signs and symptoms such as fever, weight loss, and anemia are uncommon.

Histologically, localized HV-CD manifests with massive lymph node hyperplasia, involuted germinal centers, and marked capillary proliferation with endothelial hyperplasia. These masses are typically hypervascular with large feeding vessels. Localized HV-CD can affect any thoracic compartment, but the middle mediastinum and hila are most commonly involved.

Imaging studies show one of three morphologic patterns:

- Solitary mass (50%)
- Dominant infiltrative mass with associated lymphadenopathy (40%)
- Diffuse lymphadenopathy confined to a single mediastinal compartment (10%)

Identification of the first pattern suggests that complete surgical resection is likely. Identification of the second or third pattern suggests that complete excision may be difficult or impossible.

On non-contrast-enhanced CT, localized HV-CD manifests as a homogeneous or heterogeneous mass of soft tissue attenuation. Calcification is uncommon (5% to 10%) and is typically coarse and central in location. HV-CD typically enhances intensely following IV administration of iodinated contrast material (Fig. 29–94). On MRI, the lesions are typically heterogeneous and show increased signal intensity (compared to skeletal muscle) on T1-weighted sequences. They become markedly hyperintense on T2-weighted sequences. Low signal intensity septa are occasionally visible. In larger lesions, flow voids in and around the mass may be identified and are important clues to the hypervascular nature of the lesions. Because the lesions are hypervascular, diffuse enhancement following administration of IV gadolinium is common (Fig. 29–95).

Disseminated Castleman's Disease. Disseminated Castleman's disease is currently regarded as a potentially malignant lymphoproliferative disorder that has been associated with the *POEMS syndrome* (polyneuropathy, organomegaly, endocrinopathy, monoclonal proteinemia, and

Figure 29–94. Hyaline-vascular Castleman's disease. A, CT performed to direct a biopsy on a patient in the prone position shows heterogeneous soft-tissue-attenuation mass in the left posterior mediastinum (arrowheads). The biopsy needle (arrow), central linear calcification, and left pleural effusion can be seen. B, Contrast-enhanced CT with the patient supine shows intense enhancement within the mass as well as a small associated pretracheal node (arrow).

Figure 29-95. Hyaline-vascular Castleman's disease. **A**, Coronal T1-weighted MR image shows large, homogeneous mass (arrowheads) in subcarinal region of intermediate signal intensity. Note mass effect on the carina. **B**, Coronal T1-weighted MR image following administration of gadolinium-based contrast material demonstrates diffuse enhancement within the mass, typical of hyaline vascular Castleman's disease. T, trachea.

skin changes), osteosclerotic myeloma, Kaposi's sarcoma, and acquired immunodeficiency syndrome (AIDS). Most patients with disseminated thoracic Castleman's disease have the plasma cell form of the disease. It affects all age groups but the peak incidence is in the fifth decade of life. Women are more commonly affected than men by a ratio of 2:1. Most patients present with systemic complaints of fever, weight loss, and anemia.

Disseminated thoracic Castleman's disease usually manifests on chest radiographs as bilateral mediastinal widening. Focal mediastinal masses are rare. The anterior mediastinum is most commonly affected. On CT, diffuse lymphadenopathy involving multiple mediastinal compartments is noted (Fig. 29-96). The nodes typically range in size from 1 to 6 cm in diameter and demonstrate homogeneous attenuation on non-contrast-enhanced CT scans. As-

sociated findings such as splenomegaly or ascites are common.

Mediastinitis

Acute Mediastinitis

Acute bacterial mediastinitis is a life-threatening condition that requires prompt diagnosis and treatment. Spontaneous or iatrogenic esophageal rupture is the most common cause, accounting for up to 90% of cases. Other causes include direct spread from retropharyngeal or pleural infection and mediastinitis after cardiac surgery.^{27, 32, 88, 128, 137, 169, 209, 251, 262}

Findings of esophageal perforation on CT include peri-esophageal fluid collections (100%), extraluminal mediastinal air (100%), esophageal wall thickening (82%), and

Figure 29-96. Disseminated Castleman's disease. **A**, CT shows marked subcarinal adenopathy (arrows). Paratracheal and prevascular adenopathy was extensive (not shown). D, descending aorta. **B**, Contrast-enhanced CT shows marked enhancement of subcarinal and aortopulmonary window (arrowhead) lymph nodes. A right pleural effusion can be seen.

Figure 29-97. Acute mediastinitis after perforation of esophageal carcinoma. CT shows extravasation of esophageal contrast (EP) and air into mediastinum after perforation. A small right pleural effusion can be seen.

pleural effusion (82%) (Fig. 29-97). Pleural effusion tends to be right sided in patients with iatrogenic, midesophageal perforation and left sided in patients with spontaneous, distal esophageal perforation (Boerhaave's syndrome). The site of perforation is uncommonly visualized on CT (18%).

Descending cervical mediastinitis (DCM) is an uncommon but life-threatening cause of mediastinitis. Such infections begin in the head and neck region and spread via fascial planes into the mediastinum, usually in the prevertebral space; from there, the infection spreads into the middle and posterior mediastinum. Typical causes include odontogenic infection as well as suppurative tonsillitis and adenitis and retropharyngeal abscess. CT performed in patients with DCM shows fluid collections in the mediastinum that may be contiguous with fluid collections in the cervical region (Fig. 29-98). CT is essential for confirming the diagnosis; it assists in fluid aspiration to confirm infection and in monitoring the patient's response to therapy.

Figure 29-98. Descending cervical mediastinitis. CT shows air-containing mediastinal abscess (AB) that extended from an abscess in the neck.

Figure 29-99. Mediastinal hematoma mimicking mediastinal abscess after coronary artery bypass procedure. Contrast-enhanced CT shows well-circumscribed soft tissue abnormality in the fat of the anterior mediastinum (arrowheads). Small focal adjacent air collections (arrow) and surgical clips anterior to the ascending aorta can be seen. The needle aspirate confirmed hematoma and the culture was negative for organisms. A, ascending aorta; P, main pulmonary

Mediastinitis after cardiac surgery is uncommon, occurring in only 0.5% to 1% of patients.^{25, 69, 208} CT is frequently performed in patients with clinically suspected mediastinitis, but it can be difficult to interpret because fluid and air collections, hematomas, pleural effusions, and increased attenuation of anterior mediastinal fat, all potential findings of mediastinitis, are common and expected findings in the immediate postoperative period. These findings generally resolve, however, in the first days and weeks after median sternotomy.

Needle aspiration of fluid collections may be necessary to rule out infection when mediastinitis is suspected (Fig. 29-99). CT is most useful for distinguishing patients with significant retrosternal fluid collections that require open drainage from those who have only superficial wound infections (Fig. 29-100). CT, however, has limited ability for detecting early changes of sternal osteomyelitis.

Histoplasmosis and tuberculosis can cause acute pericarditis and mediastinitis. As in mediastinitis of any cause, the CT appearance is that of increased attenuation of mediastinal fat, focal fluid collections, or abscesses (Fig. 29-101). Infected lymph nodes can show low attenuation centers and peripherally enhancing rims.

Fibrosing Mediastinitis

Mediastinal fibrosis (sclerosing or fibrosing mediastinitis) is a rare benign disorder caused by proliferation of acellular collagen and fibrous tissue within the mediastinum.^{62, 160, 208, 210, 228, 259} An abnormal immunologic response to antigens of *Histoplasma capsulatum* is thought to be the most common cause in the United States. Other causes include *M. tuberculosis* infection, autoimmune disease, radiation therapy, trauma, and drugs such as methysergide. A rare familial form associated with retroperitoneal fibrosis,

Figure 29-100. Mediastinitis manifesting as mediastinal abscess. CT shows a poorly margined heterogeneous soft tissue mass (arrowheads) in the anterior mediastinum. Note the absence of air within the abscess. The needle was positive for *Staphylococcus aureus* infection. B, brachiocephalic artery; S, superior vena cava.

Figure 29-101. Acute mediastinitis caused by histoplasmosis. CT shows diffuse increased attenuation of mediastinal fat and pericardial effusion (E).

Figure 29-102. Mediastinal granuloma caused by histoplasmosis. CT shows soft-tissue-attenuation mass with punctate calcification (arrowheads) in the superior mediastinum. Biopsy confirmed histoplasmosis. T, trachea.

Figure 29-103. Fibrosing mediastinitis in a 45-year-old woman with chest pain. *A*, CT of the chest demonstrates an infiltrating right hilar mass (arrowheads) with punctate calcification and right posterior pleural thickening. *B*, Axial T1-weighted MR image shows intermediate-signal-intensity mass (arrowheads) and obstruction of the right pulmonary artery. The MRI appearance is nonspecific; the presence of extensive calcification on the CT scan suggests the diagnosis. A, ascending aorta; P, pulmonary artery. (Reprinted with permission from Erasmus JJ, McAdams HP, Donnelly LF, Spritzer CE: MR imaging of mediastinal masses. *Magn Reson Imaging Clin North Am* 8:59-89, 2000.)

sclerosing cholangitis, Riedel's thyroiditis, and pseudotumor of the orbit is also reported.

Affected patients usually present in the second through fifth decades of life with signs and symptoms caused by obstruction and compression of the SVC, pulmonary veins or arteries, central airways, or esophagus. Patients most commonly present with cough, recurrent pulmonary infection, hemoptysis, or chest pain. Pulmonary venous obstruction may result in symptoms that mimic those of mitral stenosis.

The chest radiographic findings of fibrosing mediastinitis are nonspecific and often underestimate the extent of mediastinal disease. CT and MRI are consequently useful in the evaluation of this disorder (Figs. 29-102 to 29-104). On CT, fibrosing mediastinitis typically manifests as an infiltrative, often calcified hilar or mediastinal process. CT is useful for demonstrating airway, pulmonary arterial and venous involvement.

On MRI scans, the process typically shows heterogeneous signal intensity on T1-weighted and T2-weighted images. Markedly decreased signal intensity on T2-weighted images is occasionally seen and is suggestive of the fibrotic nature of the process. MRI may be superior to CT for defining the full extent of the disease, which is of importance in preoperative planning; however, CT is better for demonstrating calcification within the lesion, a finding that is critical for differentiating fibrosing mediastinitis from other infiltrative disorders of the mediastinum such as metastatic carcinoma or lymphoma.

Hemorrhage

Bleeding can occur within the mediastinum as a result of trauma, surgery, or line placement; after endoscopy; or as a result of abnormal clotting factors. Hemorrhage may

extend from the neck or retroperitoneum into the mediastinum. Hemorrhage can manifest as diffuse areas of increased density or as focal areas of increased density within the mediastinal fat.

Mediastinal Lipomatosis

Mediastinal lipomatosis is a benign accumulation of fat within the mediastinum that can manifest as widening of the mediastinum on chest radiographs.¹²⁴ Mediastinal

Figure 29-104. Posterior mediastinal fibrosis. CT shows diffuse soft-tissue-attenuation mass encasing the distal aorta (D) and extending into the pleural space (arrowhead) bilaterally. Extensive calcification (arrow) can be visualized in the right pleural space.

Figure 29-105. Mediastinal lipomatosis. CT shows bilateral mediastinal widening caused by mediastinal fat deposition. Fat deposition is also visible in the paraspinal and posterior pleural regions bilaterally (arrowheads). The distribution is typical of mediastinal lipomatosis. A, aorta; S, superior vena cava; T, trachea.

lipomatosis may be associated with obesity, steroid use, or Cushing's syndrome, but often no predisposing factor is recognized. The accumulation of fat is more pronounced in the upper mediastinum. Mediastinal lipomatosis demonstrates a uniform fat density of -100 HU on CT (Fig. 29-105). If the fat has a higher density or strands of soft tissue density within it, other diagnoses, such as liposarcoma, hemorrhage, tumor infiltration, or mediastinitis, should be considered.

Occasionally, a prominent epicardial fat pad can result in a mediastinal mass (Fig. 29-106).

Mesenchymal Tumors

A variety of mesenchymal tumors can arise in the mediastinum and affect one or multiple compartments.^{38, 54, 59, 111, 176, 249} These include malignancies such as leiomyosarcoma and liposarcoma as well as benign desmoid tumors of the mediastinum.

Figure 29-106. Cardiophrenic angle mass. CT shows that this mass is caused by a prominent epicardial fat pad (FP).

Figure 29-107. Mediastinal liposarcoma. Contrast-enhanced CT shows a large heterogeneous mediastinal mass involving multiple compartments. Note enhancing septa (arrows) and absence of adipose tissue within mass. A, aorta; S, superior vena cava.

Liposarcomas typically arise in the anterior mediastinum, occur in middle-aged adults, and present with symptoms of chest pain and dyspnea. Masses are typically large and diffusely infiltrate the mediastinum. Low-grade tumors can have large amounts of fat demonstrable on CT or MR images; high-grade tumors typically manifest as heterogeneous soft tissue masses on CT or MR images (Fig. 29-107).

Leiomyomas and leiomyosarcomas usually arise from the esophagus, although rarely they can arise in the mediastinum independent of the esophagus. They manifest as large middle-mediastinal masses of soft tissue attenuation or signal intensity on CT or MR images. Affected patients typically present with dysphagia.

Other less common mesenchymal sarcomas that may

Figure 29-108. Primary mediastinal sarcoma. CT shows large, lobular, heterogeneous anterior mediastinal mass. The fat plane (arrowheads) between the mass and the adjacent compressed heart (H) is preserved.

Figure 29-109. Diffuse mediastinal metastases. Contrast-enhanced CT shows diffuse infiltrating mediastinal mass caused by metastatic breast carcinoma. Narrowing of the superior vena cava (asterisk), chest wall metastasis (arrowhead), and large right pleural effusion can be seen. A, ascending aorta; D, descending aorta; R, right main bronchus.

arise within the mediastinum include rhabdomyosarcoma, fibrosarcoma, chondrosarcoma, and osteosarcoma (Fig. 29-108).

Desmoid tumors are uncommon proliferations of fibroblastic cells that typically arise from muscular fascia. Although histologically benign, they can exhibit aggressive behavior with a propensity for local invasion and recurrence after resection. They uncommonly arise within the

mediastinum. Most tumors that affect the mediastinum do so by extension from chest wall or head and neck lesions. On CT, desmoid tumors are usually homogeneous and show slightly increased attenuation relative to skeletal muscle. On T1-weighted MR images, they show low signal intensity; on T2-weighted images, they show variable signal intensity. Although the tumors are usually localized, extensive invasion of mediastinal structures is occasionally detected.

Metastatic Malignancy

Metastatic malignancy can occasionally result in a diffuse mediastinal abnormality. This most likely results from extranodal extension in patients with metastatic disease to the mediastinal lymph nodes. Metastatic mucinous tumors to the mediastinum (ovarian, colon) can occur in young patients, and occasionally this occurs prior to the diagnosis of the primary malignancy. Metastatic malignancy appears on CT or MR images as an infiltrating, heterogeneous mass that invades and occasionally obliterates adjacent mediastinal structures (Fig. 29-109). It can be difficult to differentiate metastatic malignancy from fibrosing mediastinitis. Features that suggest fibrosing mediastinitis rather than metastatic malignancy include the following:

- Diffuse calcification within the lesion
- Young age of patient
- No history of extrathoracic primary malignancy

Vascular Abnormalities and Anomalies

A variety of vascular anomalies can simulate a mediastinal mass.^{42, 43, 98, 99, 260, 261} These include, but are not limited to, dilation of the pulmonary arteries, dilation of the vena cava, persistence of a left SVC, a persistent vertical vein, the SVC syndrome, dilation of the azygos or hemiazygos veins, mediastinal varices, aneurysms and pseudoaneurysms of the aorta, right-sided and double aortic arches, aberrant subclavian arteries, and tortuous great vessels. In all cases, CT (usually with IV contrast material) or MRI is essential for confirming the diagnosis (Fig. 29-110).

Figure 29-110. Esophageal varices. A and B, Contrast-enhanced CT shows multiple tubular contrast-enhancing structures surrounding the distal esophagus (asterisk on A), compatible with esophageal varices. Note moderate ascites. A, aorta; S, stomach.

Figure 29-111. Azygos continuation of interrupted inferior vena cava. *A*, CT shows the dilated azygos vein (arrowheads) as it enters the posterior aspect of the superior vena cava (S). *B*, Caudal CT shows the dilated azygos vein (arrow) near the diaphragmatic hiatus. The hemiazygos vein (arrowhead) is normal. A, aorta.

Figure 29-112. Complex venous anomalies in a patient with polysplenia. *A*, Contrast-enhanced CT shows left (L) and right (R) superior venae cavae. *B*, The more caudal image shows a dilated superior intercostal vein (V) along the lateral aspect of the proximal descending aorta (D). Anterior communication with the left superior vena cava (L) can be seen. *C*, The more caudal image shows a dilated hemiazygos vein (H), suggesting interruption of the inferior vena cava, confirmed on abdominal images. A, ascending aorta; AA, aortic arch; e, esophagus; P, main pulmonary artery; T, trachea.

Azygous Continuation of Inferior Vena Cava

Interruption of the inferior vena cava is a congenital abnormality that can be associated with polysplenia.^{56, 57, 256} In this anomaly, the infrahepatic, suprarenal segment of the inferior vena cava is absent. Venous blood from the lower extremity and abdomen is diverted into the azygos, or less commonly, the hemiazygos system, resulting in dilation of these veins. Chest radiographs usually show an enlarged azygos vein and a widened paraspinal reflection, and the inferior vena cava is usually not visualized on the lateral radiograph. CT or MRI shows enlargement of the azygos or hemiazygos veins and marked dilation of the azygos arch or the left superior intercostal vein (Figs. 29-111 and 29-112).

Persistent Left Superior Vena Cava

A persistent left SVC⁴⁴ occurs in about 1 in 200 adults with normal hearts and in up to 5% of children with congenital heart disease. Most patients with this anomaly have both a right and a left SVC. Occasionally, a persistent brachiocephalic vein connects the two superior venae cavae. On CT, the left SVC is seen as a round density just to the left of the aortic arch. If contrast material is administered via the left arm, the vein enhances (see Fig. 29-112). The left SVC extends inferiorly to the region of the left superior pulmonary veins and then connects into the coronary sinus (Fig. 29-113). Rarely, the vein may connect into the left atrium, giving rise to a small right-to-left shunt.

Figure 29-113. Persistent left superior vena cava (SVC). *A*, CT shows persistent left SVC (arrow) adjacent to the transverse aorta. *B* and *C*, The more caudal CT images show characteristic anatomic findings of the left SVC. Two vascular structures can be seen anterior to the left main bronchus (L). Left SVC (arrowhead on *B*) is anterior to the left upper lobe bronchus (asterisk on *B*), adjacent and medial to the left superior pulmonary vein (arrow in *B*). Drainage of the left SVC into coronary sinus (arrow in *C*) typically results in dilation of the sinus. Ao, transverse aorta; P, pulmonary artery; RA, right atrium.

Figure 29-114. Collateral venous channels in a patient with thrombosis of the left subclavian vein caused by an indwelling catheter. *A*, Contrast-enhanced CT shows narrowing of the left subclavian vein (arrows), numerous enlarged veins in soft tissues of the chest (small arrowheads) and paravertebral region. The large arrowhead indicates an enlarged right superior intercostal vein, and the asterisk indicates paratracheal adenopathy. *B*, Contrast-enhanced CT shows collateral venous drainage in the recanalized umbilical vein (arrow). Bilateral pleural effusions can be seen. L, liver; H, heart; S, spleen.

The persistent left SVC should not be confused with the left superior intercostal vein. The superior intercostal vein connects the left brachiocephalic vein with the hemiazygos system. It runs parallel to the aortic arch, is often seen in the fat adjacent to the arch, and normally measures no more than 4 mm in diameter. It can become enlarged as a result of collateral flow in patients with congenital or acquired obstruction of the vena cava (see Fig. 29-112).

Superior Vena Cava or Brachiocephalic Vein Obstruction

Obstruction of the SVC or brachiocephalic veins can result from malignancy, infection, or iatrogenic causes.^{23, 266} Lung carcinoma is the most common malignant cause; histoplasmosis-induced fibrosing mediastinitis is the most common infectious cause (in the Midwestern United States); and central venous catheters are the most common iatrogenic cause. In the past, upper extremity venography was the method of diagnosing SVC or brachiocephalic venous obstruction. Contrast CT is the now the most common imaging modality used (Fig. 29-114). MRI can also be useful in patients with contraindications to administration of iodinated contrast material, but it occasionally fails to differentiate complete obstruction from marked narrowing with very slow flow.

Aberrant Right Subclavian Artery

An aberrant right subclavian artery^{31, 199, 200} is a common vascular abnormality that occurs in about 1 in 200 patients. In younger patients, it is usually not obvious on a chest radiograph; in older patients, however, it can manifest as a right paratracheal mass or, on the lateral radiograph, as a retrotracheal mass—like opacity. On CT, the aberrant right subclavian artery arises as the last and most posterior vessel off the aortic arch, crosses the mediastinum behind the trachea and esophagus, and continues into the neck and axilla along the right of the trachea (Figs. 29-115 and 29-116). Frequently, a diverticulum (Kommerell's) is seen

at the origin of the aberrant right subclavian artery from the aorta.

Right Aortic Arch

A right aortic arch^{16, 167, 199} is commonly mistaken for a mediastinal mass on chest radiographs, and patients are often referred for CT evaluation of a right paratracheal mass. Most asymptomatic adults with a right-sided aortic arch have an aberrant left subclavian artery. Other anatomic configurations, such as mirror-image branching of the great vessels, are less common and more often associated with severe congenital heart disease. CT or MRI easily identifies

Figure 29-115. Aberrant right subclavian artery. Contrast-enhanced CT shows enhancement of retrotracheal right subclavian artery (R). A nasogastric tube can be seen in the esophagus (arrow). B, brachiocephalic vein; c, left and right common carotid arteries; L, left subclavian artery; S, superior vena cava; T, trachea with endotracheal tube.

Figure 29-116. Aneurysm of aberrant right subclavian artery. *A*, CT shows homogeneous soft tissue mass (arrows) with rim calcification posterior to the trachea (T). *B*, A more caudal CT image confirmed that the mass is an aneurysm of the aberrant right subclavian artery, originating from the proximal descending aorta (arrowheads). A, common origin of carotid arteries from aorta; c, left and right common carotid arteries; e, esophagus; L, left subclavian artery.

the aortic arch to the right of the trachea. The aberrant right subclavian artery arises as the last and most posterior vessel off the right-sided aortic arch, crosses the mediastinum behind the trachea and esophagus, and continues into the neck and axilla along the left side of the trachea (Fig. 29-117). Frequently, a diverticulum is seen at the origin of the aberrant left subclavian artery from the aorta.

Double Aortic Arch

Double aortic arches typically manifest in childhood with stridor.^{167, 199} Rarely, the lesion manifests in adulthood as an asymptomatic mediastinal mass. On CT or MRI, the double aortic arch is obvious as two large vascular structures encircling the trachea. Each arch gives rise to a subclavian and a carotid artery. The descending aorta is

Figure 29-117. Right aortic arch with aberrant left subclavian artery. *A*, Coronal ECG-gated MR image shows right aortic arch (R) and retroesophageal aortic diverticulum (D), giving rise to aberrant left subclavian artery. *B*, Axial ECG-gated MR image shows aberrant left subclavian artery (LS) in retrotracheal location. BC, brachiocephalic vein; R, right aortic arch; S, superior vena cava; T, trachea. Asterisks indicate the esophagus.

Figure 29-118. Calcified left ventricular aneurysm. CT shows a thin, curvilinear calcification (*arrow*) in the left ventricular apex, consistent with left ventricular aneurysm resulting from a prior infarction. LV, left ventricle; RV, right ventricle.

usually on the left, and the right arch is often higher and slightly larger than the left arch.

Left Ventricular Aneurysm and Pseudoaneurysm

Aneurysms and pseudoaneurysms of the left ventricle¹⁰⁴ often present as mediastinal masses. True left ventricular aneurysms are caused by myocardial ischemia and infarction resulting in focal thinning, dilation, and paradoxical motion of the affected portion of the ventricle. True aneurysms usually occur in the distribution of the left anterior descending coronary artery (along the anterior and apical walls of the left ventricle) and frequently calcify. On CT, they manifest as broad-based areas of thinning of the anterior or apical walls of the left ventricle, often with associated calcification (Figs. 29-118 and 29-119). Mural thrombus may be identified adjacent to the aneurysm. Cine MRI can be useful for demonstrating paradoxical wall motion in the region of the aneurysm.

Figure 29-119. Calcified left ventricular aneurysm with apical thrombus. Contrast-enhanced CT shows a thin curvilinear calcification (*white arrowhead*) in the left ventricular apex, consistent with left ventricular aneurysm. Focal wall thinning and adjacent apical thrombus (*black arrowheads*) can be seen.

Figure 29-120. Left ventricular pseudoaneurysm. Contrast-enhanced CT shows a large pseudoaneurysm arising from the posterior wall of the left ventricle. A narrow neck (*arrowheads*) between the pseudoaneurysm (A) and the left ventricular cavity (LV) is seen.

Left ventricular pseudoaneurysms result from perforation of the ventricular wall after myocardial infarction. The perforation is contained by pericardium, resulting in pseudoaneurysm formation. Pseudoaneurysms more commonly occur along the posterior and inferior surfaces of the heart and infrequently calcify. On contrast-enhanced CT, they manifest as focal enhancing masses along the posterior or inferior surface of the ventricle, with a narrow communication with the left ventricular chamber (Fig. 29-120). It is important to differentiate pseudoaneurysms from true aneurysms, as the former are prone to delayed rupture whereas the latter are not.

Diaphragmatic Hernia

Abdominal organs or retroperitoneal fat can herniate through areas of congenital or acquired diaphragmatic weakness or tears and manifest as a mediastinal mass on chest radiographs.^{71, 82, 83} Common nontraumatic sites of

Figure 29-121. Hiatal hernia. CT shows herniation of a portion of the stomach (HH) through the esophageal hiatus.

Figure 29-122. Morgagni's hernia. A and B, CT shows herniation of omental fat (arrowheads) into the right cardiophrenic angle. Omental vessels are seen within the fat. L, liver.

herniation include the anterior parasternal hiatus, the esophageal hiatus, and the posterior pleuroperitoneal hiatus. Hiatal hernias are a common cause of a middle mediastinal mass in the lower thorax. The diagnosis is easily made if air or contrast material is seen within the hernia (Fig. 29-121).

Herniation through the anterior parasternal hiatus (foramen of Morgagni) is uncommon and usually manifests as a right-sided mediastinal or cardiophrenic angle mass (Fig. 29-122). These defects are more commonly identified in middle-aged to older adults and are typically asymptomatic. Rarely, defects occur on the left or into the pericardium.

Herniation through the posterior pleuroperitoneal hiatus (foramen of Bochdalek) is the most common cause of congenital diaphragmatic hernia in infants. In adults, the lesions are usually small and asymptomatic and occur more commonly on the left (65%) than on the right (35%). The incidence of small, posterior, fat-containing defects increases with age and degree of emphysema (Fig. 29-123).

Figure 29-123. Bochdalek's hernia. CT shows homogeneous fat-attenuation mass (arrowheads) in the right paraspinal location. Location and CT appearance are consistent with a diagnosis of Bochdalek's hernia. A, aorta.

Pleura and Chest Wall

Barbara L. Knisely

After the initial chest radiograph, computed tomography (CT) is the standard imaging modality for the evaluation of chest wall disorders and pleural disease. CT characterizes the type of pleural disease by tissue density, evaluates the extent of pleural and chest wall disease, and differentiates between pleural and parenchymal disease.³⁵ Magnetic resonance imaging (MRI), with its superior soft tissue contrast, complements CT in patients with pleural disorders. The role of MRI in the chest is limited to specific problem solving, such as select cases of pleural effusions, tumors, infections, and masses.^{37, 41} The ability of MRI to obtain images in the coronal and sagittal planes helps in the evaluation of chest wall and pleural abnormalities, particularly the apical regions.^{15, 34, 48, 70}

This chapter discusses the CT and MRI findings of pleural and chest wall diseases.

CT Technique

Standard CT examination of the chest includes 10-mm collimation with 10-mm slices obtained from the thoracic inlet through the adrenal glands. Images are obtained with the patient supine in the scanner and with respiration suspended. Helical CT scanners can image the entire chest in a single breath-hold, diminishing respiratory artifact. Coronal and sagittal planes may be reconstructed from the helical CT data for improved evaluation of the pleura and chest wall.

The use of intravenous (IV) contrast is tailored to the individual examination. Contrast may add information in differentiating empyemas from lung abscesses, in distinguishing among solid and cystic lesions, and in identifying areas of necrosis. Images are reviewed in both lung and mediastinal window settings. High-resolution CT (HRCT) images are obtained using 1-mm slices and a high spatial algorithm to evaluate for such diseases as asbestosis in the setting of asbestos exposure.

MRI Technique

There is no standard technique used for the MRI evaluation of chest wall and pleural disease. Common sequences may be as follows:

1. T1-weighted spin-echo (SE) sequences, with a repetition time (TR) of 400 to 600 msec and an echo time (TE) of 15 to 20 msec.
2. Proton-density-weighted and T2-weighted spin-echo sequences (2200–2700/20–30, 80).

3. Fast spin-echo techniques (4000–5600/80–104; 8–12 echo train).

Fat saturation, flow compensation, and presaturation inferiorly and superiorly are added to these sequences. Sequences employed in vascular assessment are as follows:

1. Short tau inversion recovery (STIR) sequences (TR/TE/TI, 2200/43/160 msec).
2. Gradient-recalled acquisition in the steady state (GRASS) sequences (33/13, 30 degrees flip angle).

The slice thickness and intersection gap vary for each examination, depending on the region of interest. The imaging planes (sagittal, axial, coronal, and oblique) are chosen to best depict the anatomy and the abnormality.

Chest MR images are obtained with a large field-of-view scout, usually in the coronal plane, with the patient in either a torso or a body coil. Cardiac gating techniques and respiratory compensation are routinely used. Pulse sequences, imaging planes, and section thickness are designed for the individual patient.

Generally, T1-weighted images provide good anatomic resolution and superb contrast between abnormalities in the extrapleural and pleural fat.^{27, 42} T2-weighted images offer good tumor-to-muscle contrast and are helpful in evaluating pleural diseases that invade the chest wall. Additional images with a smaller field of view may be obtained after the initial views with the use of specialized surface coils.

Pleura

Routine CT and MRI cannot perform imaging of the pleura. HRCT depicts the intercostal stripe as a 1- to 2-mm soft tissue line running along the inner aspect of the ribs. This stripe is composed of the visceral and parietal pleura, endothoracic fascia, and the innermost intercostal muscle.³³ The extrapleural fat is seen on HRCT internal to the ribs and is more prominent in obese patients.

Pleural Processes

The features of pleural processes often overlap with parenchymal or extrapleural processes on radiographs. Rib destruction and soft tissue involvement characterize an extrapleural process. Parenchymal lesions typically result in an acute angle with the mediastinum or chest wall.⁴² In contrast, pleural processes usually result in an obtuse angle with the chest wall. Despite these general rules, differenti-

ating pleural, extrapleural, and parenchymal processes on CT and MRI may be difficult because more than one compartment may be involved.

Pleural Effusions

A pleural effusion produces a crescent-shaped opacity in the posterior dependent thorax. Loculated pleural effusions appear as fixed lenticula-shaped opacities. Free-flowing pleural fluid in the posterior costophrenic angle may be difficult to differentiate from ascites.

A number of CT signs have been reported to help differentiate pleural from ascitic fluid, namely (1) the diaphragm,⁴ (2) the interface,⁷⁵ (3) a displaced crus,¹⁹ and (4) a "bare area" sign.⁵³ The interface and bare area signs are the most accurate.²⁹

The interface sign describes a hazy interface with a pleural effusion and a sharp interface with ascites adjacent to the liver or spleen (Figs. 30-1 and 30-2).⁷⁵

The bare area sign describes the restriction of ascites from contacting the posterior liver by the coronary ligaments in the right hemithorax; however, pleural effusion can freely flow in that location.⁵³

The diaphragm sign describes the anatomic location of pleural effusion relative to the diaphragm. Pleural effusion is outside the diaphragm, and ascites is inside the diaphragm (see Fig. 30-2).⁴

The displaced crus sign describes the anterolateral displacement of the crus by the pleural effusion, which is located between the crus and the spine (Fig. 30-3).¹⁹ Ascites would cause the opposite displacement of the diaphragmatic crus. On an axial image, ascites is contained within the confines of the diaphragm, whereas effusion lies outside the confines of the diaphragm.

Pleural fluid commonly is heterogeneous on MRI scans because flow artifacts are created by motion within the effusion. Simple pleural effusions show low signal intensity on T1-weighted images and high signal intensity on T2-

Figure 30-2. CT of "diaphragm" and "interface" signs. Ascites (A) is medial to the diaphragm (arrow), and a pleural effusion (E) is identified lateral to the diaphragm. A sharp interface can be seen between the ascites and the spleen (arrows).

weighted images because of their water content.² CT is currently the study of choice for the evaluation of pleural fluid. However, one study showed that MRI may be slightly superior to CT in the characterization of pleural fluid.¹⁷ The MRI signal intensity of pleural effusions differentiates *transudates* from *exudates*, with exudates producing a higher signal intensity, particularly on T2-weighted images.¹⁷

Acute, hemothorax shows high attenuation within the pleural fluid on a nonenhanced CT scan (Fig. 30-4). A fibrothorax may develop if a hemothorax is not drained and is allowed to organize, resulting in pleural thickening. A subacute or chronic hemothorax (Fig. 30-5) demonstrates high signal intensity on both T1-weighted and T2-weighted images.⁷⁷ The "concentric ring" sign present in a subacute or chronic hemorrhagic pleural effusion is caused by the dark outer ring (hemosiderin) and the bright

Figure 30-1. CT scan of the "interface" sign. The interface between the pleural effusion and liver laterally is hazy (arrows). A sharp interface would exist between ascites and the liver.

Figure 30-3. CT of "displaced crus" sign. Right pleural effusion forms a crescent-shaped opacity in the dependent portion of the thorax. Lateral displacement of the diaphragmatic crus (arrow) describes the displaced crus sign of a pleural effusion.

Figure 30-4. Hemothorax following endomyocardial biopsy in a 59-year-old man who developed mild shortness of breath after the biopsy. Nonenhanced CT scan shows a high-attenuation left pleural effusion consistent with hemothorax (arrow). The patient recovered without intervention. (From Knisely BL, Mastey LA, Collins J, Kuhlman JE: Imaging of cardiac transplantation and complications. Radiographics 19:321, 1999.)

central signal intensity (methemoglobin) related to the T1 shortening effects.^{28, 42}

On CT scans, chylothorax usually cannot be differentiated from other types of pleural effusions, although one report did show low-attenuation fluid in a chylothorax related to its fat content.² Occasionally, a chylothorax may

show high signal intensity on T1-weighted and on proton-density-weighted images and lower signal intensity on T2-weighted images related to fat content.² On MRI, however, chylothoraces usually cannot be differentiated from simple pleural effusions.

Pleural effusions may be transudates or exudates. The visceral and parietal pleura enhance in exudative effusions, coined the *split-pleura sign*. Transudates do not usually demonstrate pleural enhancement.

Empyemas are characterized on CT by the split-pleura sign, pleural thickening, and air within the pleural space (Fig. 30-6).⁷² Empyemas are often associated with parenchymal disease. It may be difficult to differentiate between the two processes. Differentiation is important; patients with empyemas require chest tube drainage, whereas patients with lung abscesses need antibiotics and postural drainage. CT findings that indicate abscess are a spherical shape, thick walls, and abrupt cut-off of vessels and bronchi in adjacent lung at the interface with the abscess.⁷² Empyemas are lenticular, usually with thin walls and with compression of adjacent lung bronchi and vessels.^{7, 42} Thickened and increased attenuation of the extrapleural fat can be seen in patients with empyemas and is thought to be related to edema.⁸⁰

Malignant neoplasms that arise in the walls of chronic empyemas (most commonly tuberculous empyemas) may be detected by MRI.⁴⁴ Neoplasms associated with empyemas include non-Hodgkin's lymphoma, squamous cell carcinoma, mesothelioma, and sarcoma.⁴⁴ MRI reveals signal intensities that differ in mature fibrous tissue and in neoplastic tissue, yet the diagnostic value of this potential has not been determined.⁴⁴

Figure 30-5. Extrapleural hematoma in a 54-year-old woman. Axial T1-weighted (TR = 810 msec, TE = 14 msec) (A) and T2-weighted (TR = 4225 msec, TE = 105 msec) (B) images show old extrapleural hematoma as a focal ovoid mass with focal areas of increased signal intensity on T1-weighted images and a low-signal-intensity rim on T2-weighted images. The extrapleural location is identified by the displaced subpleural fat line on T1-weighted images (small arrow in A). A pleural effusion, with heterogeneous signal intensity on T1-weighted and T2-weighted images, is medial to the extrapleural hematoma (large arrow in A and B). (A and B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. MRI Clin North Am 8:125, 2000.) C, Noncontrast CT scan shows a high-attenuation right extrapleural hematoma (small arrows) and a medial simple pleural effusion (large arrow).

Figure 30-5. Extrapleural hematoma in a 54-year-old woman. Axial T1-weighted (TR = 810 msec, TE = 14 msec) (A) and T2-weighted (TR = 4225 msec, TE = 105 msec) (B) images show old extrapleural hematoma as a focal ovoid mass with focal areas of increased signal intensity on T1-weighted images and a low-signal-intensity rim on T2-weighted images. The extrapleural location is identified by the displaced subpleural fat line on T1-weighted images (small arrow in A). A pleural effusion, with heterogeneous signal intensity on T1-weighted and T2-weighted images, is medial to the extrapleural hematoma (large arrow in A and B). (A and B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. MRI Clin North Am 8:125, 2000.) C, Noncontrast

Figure 30-6. Empyema in a 49-year-old man. Contrast-enhanced CT scan shows the split-pleura sign with enhancement of the visceral (V) and parietal (P) pleura. Air bubbles are present in the empyema.

Pleural Air

Standard chest radiographs are the most commonly used radiologic examination for detection of pneumothoraces. In the supine, ventilated, or acutely traumatized patient, CT may detect pneumothoraces not visible on chest radiographs.⁷⁶

A bronchopleural fistula is a communication between the pleura and bronchial tree that results in a persistent air leak (Fig. 30-7). Common causes include necrotizing pulmonary infections and surgical lung resections. CT, particularly thin-section CT, is the imaging modality of choice to show the communication between the airway and the pleura.⁸² CT can demonstrate the location, number, size, and underlying cause of bronchopleural fistulas.⁷³

Therapeutic options include surgical resection and surgical or image-guided occlusion of the bronchopleural fistula with endobronchial vascular coils or glue. Antibiotics are given to patients with an underlying infection.⁵⁶

Pleural Masses

Benign Pleural Masses

Benign pleural processes include lipoma, asbestos-related disease, localized pleural fibroma, and rounded atelectasis.^{40, 83} The most common benign chest wall neoplasms are lipoma and localized pleural fibroma.

On CT scans, lipomas have a homogeneous fat attenuation, occasionally with a few septa or calcifications in areas of fat necrosis. Lipomas are usually located in the lateral pleura, with signal intensity characteristics of subcutaneous fat on all MRI sequences. Benign fibrous tumors of the pleura (previously termed *benign mesotheliomas*) are not asbestos-related and occur in the sixth and seventh decades of life.²⁰ Most patients with benign pleural fibromas are asymptomatic. Large pleural fibromas may produce symp-

Figure 30-7. Pleuromediastinal cutaneous fistula in a 51-year-old man with coagulase-negative staphylococcal sternal wound infection 10 days after cardiac transplantation. A, CT scan shows subcutaneous empyema in the left chest wall. B, Nonenhanced CT scan obtained inferior to A shows air in the sternal dehiscence and in infiltrated anterior mediastinal fat, findings consistent with infection. C, CT scan obtained inferior to B shows more extensive pneumomediastinum and a right pneumothorax. (From Knisely BL, Mastey LA, Collins J, Kuhlman JE: Imaging of cardiac transplantation and complications. *Radiographics* 19:321, 1999.)

Figure 30-8. Benign pleural fibroma. Enhanced CT scan reveals a soft tissue intrafissural mass with coarse calcifications, pathologically consistent with a benign pleural fibroma. (From Knisely BL, Kuhlman JE: Radiographic and CT imaging of complex pleural disease. *Crit Rev Diagn Imaging* 38:1, 1997.)

toms of cough, chest pain, and dyspnea. These tumors are associated with an increased incidence of episodic hypoglycemia and hypertrophic pulmonary osteoarthropathy.^{9, 20}

On microscopic examination, 60% of pleural fibromas are found to be benign with 40% malignant.²⁰ A malignant pleural fibroma may have an associated pleural effusion and may grow to more than 10 cm in diameter.²⁰ Chest wall invasion and local recurrence following surgery can occur with malignant pleural fibromas. The cure rate with surgical excision is 40% for malignant fibromas and 100% for benign fibromas.^{20, 50}

The CT appearance is a homogeneous, enhancing soft tissue mass with occasional calcification and associated pleural effusion (Fig. 30-8).⁶³ On MR images, pleural fibromas are isointense to muscle on T1-weighted images

and isointense to hyperintense to muscle on T2-weighted images, and they demonstrate enhancement with IV gadolinium.^{23, 39}

Rounded atelectasis (Fig. 30-9) refers to masslike atelectasis abutting the pleura. It has most commonly been described as being related to asbestos exposure.^{64, 71} Rounded atelectasis is most commonly seen in the posterior or posteromedial lower lobe, followed by the lingula and right middle lobe.¹³ The “comet-tail sign” of vessels and bronchi curving into the mass is seen in both CT and MRI. Displacement of the fissures can confirm the presence of volume loss. On MRI, the signal intensity is comparable to that of liver on T1-weighted images (see Fig. 30-9).⁷⁸ The findings of rounded atelectasis on CT and MRI are vital to recognize because this condition may be similar to a pleural or parenchymal neoplasm.⁴⁵ Biopsy of rounded atelectasis may be mistaken for malignancy if findings of fibrosis are not seen on histologic examination.¹⁸

Asbestos-related disease includes simple pleural effusions, pleural plaques and thickening, rounded atelectasis, pleural or parenchymal neoplasms, and asbestosis (interstitial lung disease).¹ Pleural plaques, the most common and specific finding, are located along the diaphragmatic and chest wall parietal pleura.⁶⁵ Calcification of pleural plaques may occur; calcifications range in thickness from 1 to 10 mm (Fig. 30-10). Diffuse pleural thickening, which may also be seen in asbestos exposure, frequently follows an asbestos-related benign pleural effusion. On CT scans, pleural plaques are recognized as focal soft tissue masses located inferiorly along the paravertebral pleura. A fibrothorax related to previous hemorrhage or infection should be the primary differential diagnosis if unilateral, thicker, more irregular calcified pleural plaques are present in a patient without a history of asbestos exposure.

Malignant Pleural Masses

Malignant mesothelioma (Fig. 30-11) is a highly lethal tumor whose increased incidence is related to the industrial use of asbestos.³¹ CT imaging of mesothelioma shows

Figure 30-9. Rounded atelectasis in a 65-year-old man. A, Contrast-enhanced CT scan reveals right pleural effusion and right lower lobe mass of atelectatic lung with incurving bronchi and vessels. B, Axial T1-weighted (TR = 400msec, TE = 14 msec) image shows an ovoid mass (large arrow) with an inwardly curving bronchovascular structure (small arrow) in the right lower lobe. The mass demonstrates isointense signal intensity relative to liver. A large right pleural effusion can be seen posteriorly. (B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-10. Asbestos exposure. Contrast-enhanced CT scan shows bilateral calcified pleural plaques posteriorly with involvement of the left diaphragm.

unilateral, diffuse, nodular pleural thickening, usually with associated pleural effusion. The tumor sometimes encases the lung, extends into the fissures, and causes unilateral volume loss. MRI reveals minimal increased signal intensity on T1-weighted sequences and moderate increased signal intensity on T2-weighted sequences. Mesothelioma (Fig. 30-12) occasionally presents as an effusion without soft tissue thickening or as a discrete pleural mass.^{3, 36, 42}

MRI is superior to CT in demonstrating a solitary focus of invasion of the chest wall or endothoracic fascia and in showing invasion of the diaphragm.³¹ MRI staging of mesothelioma does not change operative planning, and CT is the standard diagnostic examination because of its cost-effectiveness.³¹ For patients who are surgical candidates,

extrapleural pneumonectomy is the procedure of choice, although the prognosis is extremely poor.

Metastatic disease is the most common neoplasm of the pleura (Fig. 30-13).^{40, 42} Lung, breast, stomach, and ovarian carcinomas are the most common sources of metastatic pleural disease.⁶² Lymphoma and thymoma may also involve the pleural surface.⁶⁸ Metastatic pleural adenocarcinoma can mimic the radiographic appearance of mesothelioma with diffuse nodular pleural thickening. Metastatic adenocarcinoma and mesothelioma may be differentiated by immunochemistry, histochemistry, and electron micros-

Pleural effusion is the most common manifestation of pleural metastases. Diffuse pleural thickening and solid pleural masses or nodules may also be seen in metastatic pleural disease.

Chest Wall

Knowledge of the cross-sectional anatomy of the chest wall allows adequate evaluation of soft tissue abnormalities (Fig. 30-14). Normal chest wall musculature, vasculature, and bony structures are well visualized on CT scans. A simple method for counting ribs on CT scans is based on identification of the *sternal angle*,³⁸ an oval high-attenuation structure lacking bone marrow. The second costal cartilages connect to the second ribs laterally and the sternal angle medially. The third to sixth ribs are counted numerically, from anterior to posterior, on the same slice.

Benign Chest Wall Lesions

Lipoma is the most common benign soft tissue mass to involve the chest wall (Fig. 30-15).⁵² On CT images, lipomas show the attenuation coefficient of fat and are well

Figure 30-11. Malignant mesothelioma in a 57-year-old man. Coronal T2-weighted (TR = 4500 msec, TE = 105 msec) with fat saturation (A) and axial T1-weighted (TR = 821 msec, TE = 14 msec) with fat saturation (B) gadolinium-enhanced images reveal nodular pleural tumor encasing the right lung, involving the pericardium (black arrow), and extending into endothoracic fascia (white arrow). (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. MRI Clin North Am 8:125, 2000.)

Figure 30-12. Malignant mesothelioma in a 64-year-old man. Coronal T1-weighted (TR = 821 msec, TE = 14 msec) (A) and sagittal T2-weighted (TR = 4054 msec, TE = 105 msec) (B) images show loculated, heterogeneous pleural effusion on T1-weighted and T2-weighted sequences. (A and B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.) Noncontrast CT scan (C) shows loculated, low-attenuation right pleural effusion.

Figure 30-13. CT of metastatic pleural disease from adenoid cystic carcinoma of the parotid gland. A large loculated left pleural effusion and a smaller right effusion can be seen. Pleural soft-tissue attenuation deposits are identified bilaterally (arrows).

circumscribed. On MRI scans, lipomas exhibit fat signal intensities, with high signal intensity on T1-weighted and proton-density-weighted images and slightly lower signal intensity on heavily T2-weighted images. STIR and fat-saturation images depict the low signal intensity of fat. Chemical shift artifact can be seen at the interface of the lipoma with the surrounding soft tissues of higher water content. A few thin, low-signal-intensity, fibrous septations may be seen within the lipoma.⁷⁴

A diagnosis of liposarcoma should be considered if there is heterogeneous signal intensity or if there are islands of soft tissue attenuation within the fatty tumor. MRI plays a role in surgical planning, allowing adequate evaluation of fatty masses that may infiltrate the chest wall or that lie near neurovascular structures.

Chest wall masses may result from anomalies of connective tissues and the lymphatic, vascular, and musculoskeletal systems.³² Hemangioma (Fig. 30-16) is a broad category of lesions composed of cavernous, venous, arteriovenous, capillary, and mixed vascular malformations.^{25, 43} Extraskel-etal hemangiomas are uncommon benign lesions located superficially in the skin or subcutaneous tissues or deep within the synovium or musculature.^{25, 43} Superficial hemangiomas have curvilinear low-signal-intensity structures on T1-weighted images and show high signal intensity on

Figure 30-14. CT anatomy of the chest wall. *A*, Counting ribs one through three, the first rib is identified on the image, which shows the medial third of the clavicle. The second and third ribs are seen posteriorly along the rib cage. The axillary sheath contains the brachial plexus branches, and the axillary artery and vein. *B*, Sternal angle (SA) is shown as a high-attenuation structure connected laterally to the second costal cartilages and ribs. The third through sixth ribs are seen on the same slice counting posteriorly. *C*, Chest wall musculature is identified at an inferior level. *A*, pectoralis major; *AS*, axillary sheath; *B*, pectoralis minor; *C*, internal and external intercostal muscles; *D*, serratus anterior; *E*, latissimus dorsi; *F*, trapezius; *G*, rhomboid.

Figure 30-15. Lipoma in a 79-year-old woman. Sagittal T1-weighted (TR = 500 msec, TE = 8 msec) (*A*) and T2-weighted with fat saturation (TR = 4000 msec, TE = 105 msec) (*B*) images show a sharply defined mass (arrow) with signal intensity identical to that of subcutaneous fat on all pulse sequences. Fat suppression is demonstrated on T2-weighted images. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-16. Chest wall hemangioma in a 2-day-old girl. Coronal T1-weighted (TR = 450 msec, TE = 12 msec) (A) and axial T2-weighted (TR = 3000 msec, TE = 102 msec) (B) images show heterogenous soft tissue mass (white arrows) involving the lateral and posterior right chest wall. High signal intensity (black arrow) on T2-weighted images is hemorrhage, as corresponding T1-weighted images (not shown) show high signal intensity. Multiple foci of high signal on T1-weighted image represent hemorrhage. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

T2-weighted images.²⁵ Muscle atrophy may be a feature of the deep intramuscular hemangiomas.²⁵

The MRI appearance of hemangiomas depends on the subtype and components of vascular elements (old blood, thrombus, hemosiderin), fat, and connective tissue.²⁵ Hemangiomas typically exhibit intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images.^{25, 32} The hyperintensity on T2-weighted images is thought to be related to stagnant or slow-flowing blood in dilated vascular beds. Arteriovenous malformations (AVMs) are characterized by tubular flow voids on T1-weighted and proton-density-weighted spin-echo sequences and by high signal intensity on gradient-recalled echo sequences.²² The MRI finding of flowing blood allows the confident diagnosis of an AVM. MRI offers superior soft tissue contrast, which is helpful in evaluating the extension of hemangiomas into muscles, subcutaneous tissues, and the chest wall.³⁷

Lymphangiomas are congenital lesions that are usually seen as a neck mass but may extend into the chest wall, axilla, extremities, and mediastinum.^{69, 85} Histologically, lymphangiomas are a sequestered collection of lymphatics separated from the remainder of the lymphatic system.⁸⁵ Lymphangiomas are locally infiltrating and often recur locally, thus making surgery difficult.⁶⁹ Operative planning requires detailed identification of the lymphangioma and its relationship to adjacent neurovascular structures and muscles.

On MRI, lymphangiomas show the signal intensity of water on all pulse sequences, reflecting the fluid content of

the dilated lymphatics.³⁷ The signal intensity of lymphangiomas is comparable to that of cerebrospinal fluid, lower than that of muscle on T1-weighted images, and higher than that of muscle or fat on T2-weighted images.⁶⁹ MRI may reveal internal septations within lymphangiomas.⁶⁹ STIR images and T2-weighted images with fat suppression show the extension and accentuate the water content of lymphangiomas.

MRI is the preferred imaging modality for evaluating lymphangiomas, especially if the administration of IV contrast medium is contraindicated.

Malignant Chest Wall Lesions

Breast carcinoma is the most common malignant soft tissue chest wall tumor.⁷⁹ Mammography is the examination of choice in the detection of breast cancer, with MRI reserved for cases of local chest wall recurrence.⁷⁹ Sarcomas (Figs. 30-17 and 30-18) are less common soft tissue tumors of the chest wall, and desmoid tumors are reported as being one of the most common chest wall sarcomas.^{10, 79} Patients with soft tissue sarcomas have a 60% 5-year survival rate, a rate that is better than that of other primary chest wall malignancies.⁵

Patients with chest wall sarcomas do not typically present with pain. Pain associated with chest wall sarcoma is a poor prognostic sign.⁵

Desmoid tumors (see Fig. 30-18), previously termed *fibromatosis*, are infiltrative, poorly circumscribed, and ill

Figure 30-17. Undifferentiated sarcoma of the right neck and superior chest wall in a 4-month-old boy. *A*, Contrast-enhanced axial CT scan shows low-attenuation mass (arrow) in the right supraclavicular fossa, causing displacement of midline structures to the left. *B*, Axial T2-weighted (TR = 3200 msec, TE = 105 msec) image shows a tumor mass (arrow) demonstrating high signal intensity relative to muscle and involving the right axilla and chest wall. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-18. Desmoid tumor in a 60-year-old man. Coronal T1-weighted (TR = 650 msec, TE = 14 msec) (*A*) and sagittal T2-weighted (TR = 2400 msec, TE = 104 msec) (*B*) images show a tumor (white arrow) in the right supraclavicular fossa, deviating the brachial plexus anteriorly (black arrow). The tumor shows slightly high signal intensity on T1-weighted and T2-weighted images relative to muscle. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-19. CT of right chest wall adenocarcinoma of unknown primary. Ovoid, soft tissue mass (arrows) has destroyed the right lateral rib and distorts the normal musculature.

Figure 30-20. CT of metastatic melanoma to the left sternoclavicular joint. Ovoid, heterogeneous soft tissue mass (arrows) destroys medial left clavicle and causes posterior compression of left bronchiocephalic vein.

defined.⁵¹ Although these tumors were once considered benign, because metastatic disease is rare, desmoids are now classified as low-grade fibrosarcomas as a result of their locally aggressive behavior.⁵⁷ The cause of desmoids is speculative; associations have been reported with estrogen therapy, pregnancy, trauma, and Gardner's syndrome.²¹ Interesting to note, spontaneous cures of desmoid tumors have been reported during menopause and menarche.⁵⁹

CT is more helpful in evaluating the extent of soft tissue chest wall tumors than in enabling a specific diagnosis.³⁵ MRI of desmoids shows a signal intensity isointense to muscle on T1-weighted, and variable on T2-weighted, sequences.¹⁴ MRI of most malignant chest wall lesions shows heterogeneous signal intensity, with mainly hypointensity on T1-weighted images and isointensity or hyperintensity on T2-weighted images, relative to subcutaneous fat.²² Irregular margins and bone or vascular invasion are common findings in malignant lesions.

Current therapy includes wide local excision, with the role of adjuvant radiation therapy undefined.¹⁰ High recurrence rates (18% to 54%) of surgically resected desmoids are seen in young patients and patients with large tumors.¹⁰

Chest Wall Masses with Rib Destruction

The differential diagnosis for a mass arising within a rib and causing a chest wall mass with rib destruction is limited.⁵⁸ Metastasis and multiple myeloma, respectively, are the first and second most common causes of a chest wall mass with associated rib destruction.⁵⁸ Metastases to the red marrow of ribs and sternum can occur from primary tumors of the lung, breast, kidney, and thyroid in adults (Figs. 30-19 and 30-20).⁷⁹ In children, the most common causes of lytic rib lesions are metastatic neuroblastoma and primary Ewing's sarcoma (Fig. 30-21).⁵⁸

Ewing's Sarcoma

Ewing's sarcoma most frequently affects adolescent boys who present with a painful and rapidly enlarging chest wall mass.⁵ Ewing's sarcoma is sometimes called a "medical tumor" because its prognosis is related to the extent of systemic rather than local disease. The overall 5-year survival of 48% is not affected by local recurrence after chest wall resection.⁵ Five-year survival decreases to 28% with distant metastases, which occur in 75% of Ew-

Figure 30-21. Ewing's sarcoma of the left chest wall in a 21-year-old man. A, Coronal T1-weighted (TR = 789 msec, TE = 14 msec) sequence shows the tumor mass as isointense to muscle. B, Axial T2-weighted (TR = 5217 msec, TE = 80 msec) sequence shows increased signal intensity. C, Coronal gadolinium-enhanced T1-weighted with fat saturation (TR = 714 msec, TE = 8 msec) sequence shows heterogeneous enhancement. A fat plane (black arrow in A) is present between the tumor and the spleen. Tumor has destroyed the left eighth rib and extends into the extrathoracic muscles (white arrows in A-C). D, Contrast-enhanced CT scan reveals the left chest wall mass, with low attenuation relative to muscle, destroying the rib. (A-C, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

ing's sarcoma patients.¹¹ Treatment includes systemic therapy and autologous bone marrow transplantation if metastatic disease is present.⁴⁶

Askin's Tumor

Askin's tumor (Fig. 30-22) is an uncommon primitive neuroectodermal neoplasm that typically presents as a chest wall or paravertebral mass in young adults.⁶¹ The tumor shares the histologic characteristics of rhabdomyosarcoma, neuroblastoma, Ewing's sarcoma, lymphoma, and small-cell osteosarcoma. It may be distinguished as a distinct pathologic entity on the basis of characteristic immunohistochemical and electron microscopic features.^{6,61}

CT and MRI demonstrate the mass as well as erosions of the ribs or vertebral bodies. Radionuclide technetium Tc 99m bone scans often reveal other occult bony involvement. On MRI scans, an Askin's tumor is seen as a heterogeneous soft tissue mass, representing areas of focal hemorrhage and tumor necrosis. The tumor exhibits a signal intensity greater than that of skeletal muscle on T1-weighted sequences and a high signal intensity on T2-weighted sequences.⁶¹

Treatment includes combinations of surgery, radiation, and chemotherapy. The overall poor prognosis is poor, however, because of the high rate of local recurrence and the development of distant metastases.^{6, 47}

Primary Tumors of the Rib

Primary malignant and benign tumors of the cartilage or bone of the rib may also present as a chest wall mass

Figure 30-23. CT scan of osteochondroma. Noncontrast CT scan reveals a heterogeneous, lobulated, calcified mass with a cartilaginous cap arising from the right third rib, consistent with an osteochondroma.

with rib destruction. These chest wall tumors include osteosarcoma, fibrosarcoma, chondrosarcoma, osteochondroma (Fig. 30-23), giant cell tumor, enchondroma, round cell tumor, hemangioma, and aneurysmal bone cyst.⁷⁹

Traumatic rib fractures (Fig. 30-24) and chest wall hematomas may have the appearance of a chest wall mass. Surgical excision of the involved rib may be necessary at

Figure 30-22. Askin's tumor of the pleura in an 18-year-old man. Axial T1-weighted (TR = 731 msec, TE = 12 msec) (A) and coronal T2-weighted (TR = 3500 msec, TE = 102 msec) (B) images show a heterogeneous soft tissue mass (white arrow) and effusion causing compressive atelectasis of the adjacent lung (black arrow). High-signal foci on T1-weighted images correspond to high-signal foci on T2-weighted axial images (not shown), consistent with hemorrhage. Coronal T1-weighted (TR = 740 msec, TE = 11 msec) contrast-enhanced image (C) shows enhancement of the pleural mass and lack of chest wall invasion (white arrow). (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-24. Nonunion of rib fracture. Contrast-enhanced axial CT scan (A) shows expansile right rib lesion with questionable chondroid matrix (arrow). Axial (B) and sagittal (C) short-tau inversion recovery (STIR) sequences show ovoid peaked high-signal lesion (arrow) involving the anterior costochondral cartilage, consistent with granulation tissue and some fluid, which pathologically corresponded with a nonunited rib fracture. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

times because differentiating the nonunion of a rib fracture from a chondroid tumor of the rib on imaging studies may be impossible. The reparative process related to a healing rib fracture may mimic an expanding neoplasm both radiologically and histologically. Rib erosion and chest wall masses may result from an expanding thoracic aneurysm, radiation osteitis, fibrous dysplasia, and eosinophilic granuloma.⁶⁶

MRI is superior to CT in determining the extent of chest wall masses and the infiltration of the bone marrow.³⁷ However, CT more accurately displays the extent of cortical bone destruction. CT is helpful in evaluating post-traumatic abnormalities (Fig. 30-25) and sternal fractures not seen on standard films.

Pancoast Tumors

A Pancoast lesion (Figs. 30-26 and 30-27) is a superior sulcus mass that involves the brachial plexus and sympathetic ganglion of the lower neck and upper mediastinum.³⁰ Lung cancer is the most common cause of Pancoast tu-

Figure 30-25. Sternal dehiscence in a 52-year-old man who sustained blunt chest trauma 17 months after cardiac transplantation. CT scan shows anterior mediastinal fluid collection consistent with resolving hematoma. (From Knisely BL, Mastey LA, Collins J, Kuhlman JE: Imaging of cardiac transplantation and complications. *Radiographics* 19:321, 1999.)

Figure 30-26. Pancoast tumor invading the brachial plexus in a 57-year-old woman. **A.** Contrast-enhanced CT scan shows large right apical mass with central low attenuation suggestive of necrosis. Abnormal soft tissue mass extends into the axilla (arrow), consistent with chest wall involvement. **B.** Sagittal gadolinium-enhanced T1-weighted (TR = 769 msec, TE = 14 msec) image shows enhancing bronchogenic carcinoma (white arrow) invading the posterior fat plane of the brachial plexus (black arrow). (B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-27. Pancoast tumor in a 46-year-old man. Sagittal T1-weighted (TR/TE, 8958/145) (A) and sagittal T1-weighted (TR = 869 msec, TE = 14 msec) gadolinium-enhanced with fat saturation (B) sequences show left apical bronchogenic carcinoma (white arrow) invading the supraclavicular fossa, involving the brachial plexus, and encasing the subclavian artery (black arrow). (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

mors,^{32, 79} but they are also caused by metastatic disease, multiple myeloma, mesothelioma, lymphoma, and breast cancer. Pancoast syndrome is a clinical triad consisting of (1) Horner's syndrome (ptosis, miosis, anhidrosis, and enophthalmos), (2) ipsilateral arm pain, and (3) muscular wasting of the hand, which results from involvement of the nerves.⁵⁵

The superior extension of Pancoast tumors is best depicted on the coronal and sagittal MR images. MRI has an overall accuracy rate of 94% (63% for CT) for demonstrating tumoral chest wall invasion.³⁰ Streak artifact from the shoulders and the axial plane limits the evaluation of superior sulcus tumors by CT. MRI can also evaluate the tumor's relationship to the supraclavicular fossa, apical fat, subclavian artery and vein, brachial plexus, and costovertebral bony structures. Lung cancer patients with tumors invading the apex on preoperative imaging studies often receive radiation therapy to shrink the tumor prior to surgical resection.^{32, 79}

The survival rate in patients with Pancoast lung cancer has increased as a result of the combination of radiation therapy and surgery (with or without chemotherapy).³⁷

Chest Wall Invasion by Bronchogenic Carcinoma

The treatment modality of choice for lung cancer depends on the stage and histology of the tumor. Peripheral bronchogenic carcinomas invade the chest wall in only 8% of cases.⁸ Limited local invasion is resectable by either an en bloc resection of lung and chest wall or an extrapleural dissection (when tumor is limited to the parietal pleura). The soft tissue contrast resolution and multiplanar capability of MRI are superior to those of CT, making MRI slightly more accurate in the detection of tumor invasion of the chest wall.³⁰ MRI depicts tumor infiltration of the extrapleural fat and muscles of the chest wall better than CT does (Fig. 30–28). The sensitivity and specificity of MRI in the diagnosis of chest wall invasion range from 63% to 90% and 84% to 86%, respectively.^{54, 81}

T1-weighted and T2-weighted spin-echo sequences depict direct chest wall tumor extension, with improved yield on gadolinium-contrast-enhanced sequences (Fig. 30–29).²⁶ MRI is the examination of choice for the local staging of superior sulcus carcinomas, providing good anatomic detail

Figure 30–28. Bronchogenic carcinoma invading the posterior chest wall in a 94-year-old woman. T1-weighted sagittal (TR = 550 msec, TE = 16 msec) (A) and axial T1-weighted (TR = 700 msec, TE = 17 msec) (B) images show a mass (arrow) that demonstrates low signal intensity (relative to muscle) in the superior segment of the right lower lobe, invading the posterior right sixth rib and pedicle of the sixth thoracic vertebral body. (A and B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.) Contrast-enhanced CT scan (C) reveals right posterior soft tissue pedicle mass (arrows) replacing posterior right rib and thoracic body.

Figure 30-29. Bronchogenic carcinoma in a 60-year-old man. Coronal T1-weighted (TR = 600 msec, TE = 12 msec) (A) and coronal T1-weighted (TR = 800 msec, TE = 12 msec) gadolinium-enhanced (B) images show a large tumor. Signal intensity of abnormal bone marrow is seen within the thoracic vertebral bodies, consistent with tumor invasion (arrow in A), and enhancing tumor invading the apex (arrow in B) of the right chest wall. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-30. Inflammatory myofibroblastic tumor in a 15-year-old girl. A, Contrast-enhanced CT scan reveals a high-attenuation mass infiltrating the anterior chest, posterior to the right pectoralis major muscle. B, Sagittal T2-weighted (TR = 2066 msec, TE = 104 msec) image shows a mass (white arrow) that demonstrates high signal intensity (relative to muscle). It is beneath the pectoralis major muscle and infiltrates the anterior chest between the ribs, sparing the brachial plexus (black arrow). (B, From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. *MRI Clin North Am* 8:125, 2000.)

Figure 30-31. Mediastinal abscess in a 62-year-old man who developed a substernal fluid collection 6 weeks after cardiac transplantation. Contrast-enhanced CT scan shows the anterior mediastinal loculated fluid collection with air pockets. Specimen obtained from CT-guided drainage revealed gram-positive cocci, and the patient responded to antibiotic therapy and drainage. (From Knisely BL, Mastey LA, Collins J, Kuhlman JE: Imaging of cardiac transplantation and complications. Radiographics 19: 321, 1999.)

of the apices. The MRI findings of chest wall invasion include loss of the high-signal-intensity extrapleural fat on T1-weighted images and disruption of the soft tissue planes.³² High signal intensity on T2-weighted images in the muscles suggests tumor involvement, but inflammation and edema may cause similar findings.³²

Chest Wall Inflammatory and Infectious Diseases

Inflammatory myofibroblastic tumor (Fig. 30-30) is a rare pseudosarcomatous lesion that often involves the lungs of children and young adults.¹⁶ It has been reported in diverse extrapulmonary locations, specifically the trunk, and is characterized by a benign, nonmetastasizing proliferation of myofibroblasts with a potential for recurrence.¹⁶ MRI shows a lesion of intermediate signal intensity on T1-weighted sequences and increased heterogeneous signal intensity on T2-weighted sequences.²⁴

Chest wall infections are rare, yet are potentially fatal.⁶⁷ Diabetes mellitus, previous surgery or trauma, and immunocompromised states are risk factors associated with infection of the thoracic wall.⁶⁷ The prognosis is variable, depending on the length of time to make the diagnosis, the organism type, the severity of immunosuppression, and the extent of infection.⁶⁷ Physical findings of fever, focal tenderness, warmth, induration, skin discoloration, redness, or necrosis often underestimate the severity and extent of the chest wall infection, particularly in the immunocompromised patient.⁶⁷

Figure 30-32. Osteomyelitis of the sternal manubrium and left clavicle in a 75-year-old man. Axial CT scan (A) with bony windows shows erosions (black arrows) of the medial left clavicle and fistulous tract (white arrow) between the trachea and the anterior chest wall. Sagittal T1-weighted (TR = 70 msec, TE = 14 msec) image (B) and gadolinium-enhanced, T1-weighted (TR = 533 msec, TE = 14 msec) image (C) show abnormal low signal intensity (arrow in B) of the clavicular bone marrow on the T1-weighted image, contrast-enhancement of the infected bone (arrow in C), and surrounding soft tissue edema and inflammation. (From Knisely BL, Broderick LS, Kuhlman JE: MR imaging of the pleura and chest wall. MRI Clin North Am 8:125, 2000.)

Chest wall infections are categorized as cellulitis, pyomyositis, abscess, and the more life-threatening necrotizing fasciitis.⁶⁷ *Klebsiella* and *Staphylococcus* species are common and severe offending organisms in chest wall infections.⁶⁷ *Nocardia* and *Aspergillus* species, actinomycetes, *Blastomyces*, and *Mycobacterium tuberculosis* are less common pathogens affecting the chest wall.⁶⁷ CT may identify parasternal fluid collections in febrile postsurgical patients with air collections suggestive of mediastinitis and mediastinal abscess (Fig. 30–31). After surgery, fluid and the thickening of the presternal and poststernal soft tissues are seen for 2 to 3 weeks, with air resolving after 1 week.

MRI delineates the extent of soft tissue involvement and inflammation of the chest wall without requiring IV contrast agents.³⁷ Coronal and sagittal MR images are key for operative planning, identifying communications between separate, loculated abscesses and outlining the extent of the chest wall infection. On MRI, abscesses show low signal intensity on T1-weighted sequences and high signal intensity on STIR and T2-weighted sequences.³⁷ T1-weighted images yield superior spatial resolution; STIR and T2-weighted images, because of their superior contrast, are best for determining the degree of abscess extension and for defining the location of the abscess.⁶⁷ CT is much more sensitive than MRI for detecting gas in chest wall infections.³⁷

Osteomyelitis (Fig. 30–32) of the sternum, manubrium, and clavicles is optimally imaged with MRI because of its multiplanar imaging capability and superior soft tissue contrast.⁶⁷ MR images yield a sensitivity and specificity of 88% and 93%, respectively, with focal enhancement on T1-weighted fat-suppressed enhanced images indicative of osteomyelitis.⁴⁹ Infection is identified as an area of decreased signal intensity on T1-weighted sequences, com-

pared with the high signal intensity of fatty marrow, and high signal intensity on T2-weighted sequences.

IV drug abuse, diabetes mellitus, chronic renal failure, and immunosuppression predispose patients to sternoclavicular joint infections.⁸⁴ Subclavian venous catheter sequelae often lead to sternoclavicular joint infections (Fig. 30–33), with *Staphylococcus aureus* the most frequently isolated bacterium in this setting.¹²

Early cases of sternoclavicular joint infections are treated with conservative measures, including catheter removal and peripheral IV antibiotics, with a good response rate. En bloc resection is reserved for a sternoclavicular joint infection that extends beyond the joint on imaging studies.¹²

Summary

CT is the standard imaging modality in the evaluation of pleural and chest wall lesions. CT characterizes pleural effusions, differentiates parenchymal from pleural and chest wall lesions, and demonstrates areas of fatty attenuation or calcification. MRI plays a role in specific cases of tumors, infections, pleural effusions, and masses. MRI provides superior soft tissue contrast, which is helpful in determining the extent of infections and tumors involving the pleura and chest wall. MRI's multiplanar capability helps in the evaluation of chest wall and pleural abnormalities, particularly in the apical regions.

Computed Tomography and Magnetic Resonance Imaging of the Thoracic Aorta

Robert C. Gilkeson, Scott Kolodny

Imaging Techniques

As in so much of radiology, advances in cross-sectional imaging have revolutionized our ability to image the thoracic aorta. Historically, aortic imaging has been performed with contrast angiography. The technique is clearly effective in the evaluation of a variety of aortic diseases. Nevertheless, because of its invasive nature, catheter angiography is not without complications, including arrhythmia, stroke, and hemorrhage. In the modern-day radiology department, delays in the performance of conventional angiography are often longer than those for magnetic resonance imaging (MRI) and computed tomography (CT) scanning, delays that can be particularly detrimental in the trauma setting. Now, with increasingly effective MRI and CT, these techniques have largely replaced conventional angiography in the evaluation of aortic disease.

Since its inception in the late 1970s, CT has become an increasingly important modality for evaluation of disease of the thoracic aorta. Early scanners were limited by their slow acquisition times, but they quickly found a role in the evaluation of mediastinal widening, aortic trauma, and aortic disease.^{8, 40} CT evaluation of the thoracic aorta offered additional information about aortic wall thickness, surrounding mediastinal and parenchymal tissues, and disease that was not available from conventional aortography. The use of intravenous (IV) contrast agents and dynamic imaging at preselected sites in the thoracic aorta facilitated the diagnosis of aneurysmal disease and dissection.³⁹ Later in the 1980s, improvements in scanner technology and contrast delivery systems made 1- to 2-minute scanning of the thoracic aorta possible and further advanced the clinical applications of CT scanning in the thoracic aorta.¹³¹

The advent of spiral CT technology has represented the greatest advance in the rapid and accurate imaging of thoracic aortic disease.⁵⁹ With slip-ring CT technology, the patient moves continuously through the gantry while data are acquired. This technique has enabled more rapid acquisition of data, optimizing contrast enhancement of the aorta and its branch vessels. Equally important, spiral CT technology has allowed volumetric data acquisition.¹³⁹ Before spiral CT, the display of imaging data was largely limited

to the axial plane, but the spiral CT volumetric data set enables the generation of images in a variety of planes, with the capacity for three-dimensional (3D) and endoscopic images.^{56, 116} The development of spiral CT and CT angiography has been a major factor in the replacement by CT of conventional aortography for the evaluation of thoracic aortic disease.

The development of multislice CT has now allowed another quantum advance in our understanding of aortic disease. The single-detector system in traditional CT has been replaced, in multislice CT, by multidetector systems capable of acquiring multiple images in the time traditionally taken to generate one image. With most new multislice systems, imaging of the aorta can be performed four times faster than with conventional single-slice scanners. Scanning with multislice scanners that use subsecond imaging times is often eight times faster than scanning with conventional single-slice CT. The latest advances in detector technology have created eight- and 16-detector systems with rotation times of 400 to 500 msec, further decreasing imaging time and enhancing the quality of these volumetric, angiographic images of the thoracic aorta.

CT Protocols

The following three parameters are considered important in the development of protocols for CT angiography of the thoracic aorta: (1) sensitivity to intraluminal and extraluminal aortic disease, (2) maximal contrast opacification of the thoracic aorta, and (3) optimal coverage of the pertinent anatomic structures. Maximizing sensitivity to intraluminal abnormalities like atheroembolic disease and aortic dissection requires section thicknesses of 3 to 5 mm. To optimize volumetric reconstruction, reconstruction intervals between 1.5 and 2.5 mm should be used to ensure 50% overlap and optimize spatial reconstruction algorithms. Although a significant amount of research has been aimed at optimization of pitch parameters, full width at half maximum (FWHM) profiles show little degradation of image quality with pitch values up to 2.⁹³ The range of the scan should be determined by the clinical problem: If

there are suspicions about short segment narrowing, focal aneurysms, or branch vessel abnormalities, a range of 12 to 15 cm can be performed. A survey of the thoracic aorta, evaluating for the full extent of a dissection, aneurysm, or aortitis, generally requires coverage of 25 to 30 cm. Scan parameters, including pitch slice thickness and collimation, vary according to the range value and the ability of the patient to suspend respiration.

Optimal contrast enhancement of the thoracic aorta is crucial to the successful display of aortic disease. In most

cases in which single-slice spiral CT is used, injection volumes of 125 to 150 mL are needed for optimal enhancement of the selected scan volume. Nonionic contrast media are preferable at these injection rates and volumes, because they minimize the motion¹²¹ as well as the nausea and vomiting more common with ionic agents. Although earlier reports suggested injection rates of 1.5 to 2.0 mL/sec,²⁴ current literature supports injection rates of 3 to 4 mL/sec. Biphasic contrast injection protocols have been supported for consistent contrast opacification of the aortic lumen; in

Figure 31-1. A, CT tomogram of a young patient with complex congenital heart disease. There is significant cardiomegaly and a right aortic arch. Using an empiric delay for contrast injection would be inappropriate in this clinical setting. B, Axial scan demonstrating an automated bolus tracking technique shows the region of interest drawn in the ascending aorta to optimize contrast visualization. C, Automated bolus tracking technique for optimizing intravenous injection of contrast material. Arrow denotes the time to optimal contrast enhancement of the ascending aorta.

these protocols, IV contrast is injected at 4.0 mL/sec for 50 sec, and then for 2.5 mL/sec for the remainder of the scan. Some research shows this protocol to give a more uniform delivery of contrast agent for the duration of the scan. Power injectors are therefore mandatory for CT evaluation of the aorta.

A variety of researchers have studied the effect of iodine concentration on the quality of aortic opacification.^{103, 110} This work shows that there is little difference in the quality of the scans when iodine concentrations ranging from 150 to 300 mg/mL are used. Lower iodine concentrations tend to minimize venous artifacts, although the lower dilutions are often not commercially available in the United States. In our practice, we generally use an iodine concentration of 300 mg/mL; if the evaluation is being performed for suspicion of intra-aortic thrombus or atheroembolic disease, we decrease the iodine concentration to 240 mg/mL to optimize the evaluation of intraluminal disease.

There has been controversy about iodine concentration, and a variety of approaches can be used to optimize the contrast bolus. Some authors support the use of a 20- to 30-mL timing bolus to optimize contrast enhancement in the aorta. In this technique, a slice position in the aorta is preselected, and a test bolus of contrast agent is administered. Images are obtained every 2 to 3 seconds after the start of injection. A time-density curve is generated, and the time to peak opacification is determined.¹⁰⁵ Several commercially available techniques are now available that allow automated triggering of the scan without a test bolus (Fig. 31-1).¹¹³ Despite these techniques, many centers still determine injection delay times empirically. In general, a scan delay of 25 to 30 seconds in patients with normal cardiac output enables optimal contrast opacification. In patients with compromised ventricular function, a scan delay of 35 to 40 seconds is used.¹³¹

Because of significantly faster imaging times, multislice CT techniques allow for greater flexibility in determining scanning protocols for the thoracic aorta. In general, the entire thoracic aorta can be covered in 10 to 15 seconds with the multislice scanner. At our institution, we favor a 2.5-mm slice thickness, a 1.25-mm reconstruction interval, and a pitch of 1 to 1.5 cm. With a rotation time of 500 msec and slice acquisition of 2.5 mm, the thoracic aorta is evaluated in less than 15 seconds. With standard injection rates and delays, the faster imaging time enables reduction of the volume of IV contrast agent to 100 to 125 mL. When there is a concern about specific valve abnormalities or atheroembolic disease, we often decrease slice thickness to 1.25 mm but maintain a pitch of 1 to 1.5. With the advent of prospective and retrospective electrocardiographic (ECG) gating software, we can also evaluate the thoracic aorta at specific phases of the cardiac cycle, minimizing motion and valvular artifacts.

Postprocessing Techniques

With the advent of spiral CT, volumetric data sets allowed the reformatting of axial data into a variety of imaging options. These options include multiplanar reconstruction (MPR), maximal intensity projection (MIP), volume rendering, and virtual endoscopic techniques. The clinical utility of these reconstruction techniques was initially limited because of the long computer reprocessing time. Now that computer software has become faster and more sophisticated, however, these 3D techniques have become easily accessible to the general radiologist.

Multiplanar reconstructions are one-voxel-thick sections that can be processed in any obliquity (Fig. 31-2). The use of curved MPRs allows for rapid reconstructions of the

Figure 31-2. A, Sagittal multiplanar reconstruction (MPR) CT scan of the thoracic aorta. Arrow denotes the position of the sternum. Note the prominent cardiac pulsations with this conventional single-slice CT scan. B, Sagittal MPR CT scan of the thoracic aorta obtained with a multislice CT scanner. Note the lack of reconstruction artifacts in comparison with A. A = aorta; LA = left atrium; P = pulmonary artery.

Figure 31-3. Sagittal multiplanar reconstruction CT scan of the thoracic aorta in a patient with suspected pulmonary embolism. Note the prominent cardiac pulsation artifacts. A = aorta.

Figure 31-4. ECG-gated sagittal multiplanar reconstruction CT scan of the thoracic aorta in a patient with ascending aortic aneurysm. Note the absence of cardiac pulsation artifacts. Arrow denotes the ascending aorta. A = aorta; LA = left atrium.

aorta and selected branch vessels. Although MPR is the most rapid of the postprocessing algorithms, it is limited because of both partial volume effects and stair-stepping artifact due to cardiac pulsation (Fig. 31-3). This artifact can be minimized with a short reconstruction interval, and in the case of multislice scanners, retrospective cardiac gating (Fig. 31-4).

Shaded surface displays (SSDs) and MIP algorithms each have specific advantages and disadvantages in aortic

imaging. SSDs allow relatively rapid depiction of anatomic structures (Fig. 31-5), but the aortic lumen is not displayed—clearly a disadvantage in the depiction of aortic dissection and atheroembolic disease. MIP algorithms are

Figure 31-5. A, Sagittal oblique shaded surface display (SSD) shows the normal caliber of the thoracic aorta. Note the prominent cardiac pulsation artifacts in the aorta (A) and pulmonary artery (P). B, Sagittal oblique SSD of the normal thoracic aorta obtained with a multislice CT scanner. Note the absence of cardiac pulsation artifacts. Arrow denotes absence of pulsation artifacts in branch vessels.

Figure 31-6. Maximum intensity projection (MIP) of the thoracic aorta with intense enhancement of the superior vena cava (arrows), which limits evaluation of the aorta. LV = left ventricle; RV = right ventricle.

very effective at evaluating anatomy and areas of stenoses. Their utility in the thoracic aorta is somewhat limited, however, because of the close proximity of a number of high-attenuation structures, particularly mediastinal venous structures, ribs, and spine (Fig. 31-6). Postprocessing of MIP images of the thoracic aorta requires more time and may be less useful in a busy clinical practice.

Volume-rendering techniques have proved to be of greater clinical utility than other 3D techniques.¹⁰² These techniques allow accurate depictions of both the aortic lumen and surrounding structures (Fig. 31-7). Virtual endo-

scopic techniques have proved to be of great value in our practice, particularly in the setting of atheroembolic disease and for evaluation of the postoperative aorta. The use of virtual endoscopy with SSD offers rapid visualization of the aortic lumen (Fig. 31-8), whereas volume-rendered virtual endoscopy allows closer anatomic depiction along with visualization of the aortic lumen and surrounding extraluminal structures (Fig. 31-9).⁵⁵ Although volume-rendering techniques have been historically more time-consuming than SSD techniques, improved computing time have made volume rendering more viable for clinical use.

MRI

From its earliest clinical application, MRI has been an important imaging modality in the evaluation of congenital and acquired aortic disease. MRI has traditionally been a more time intensive modality compared with CT, but improvements in software, faster gradients, new breath-hold techniques, and the use of gadolinium angiography have significantly improved the efficiency of MRI in aortic imaging.

Historically, MRI has utilized “black blood” techniques for the depiction of aortic anatomy, and “white blood” techniques for the depiction of blood flow. Black blood techniques require use of ECG-gated T1-weighted spin-echo (SE) sequences. In black blood sequences, presaturation pulses are used outside the volume of interest to saturate signal from flowing blood in the aorta.⁹⁹ Axial slices are obtained at a 7- to 8-mm slice thickness from the origin of the aortic arch vessels to the diaphragm (Fig. 31-10). Sagittal oblique images are obtained as clinically indicated. In patients in whom ECG gating and breath-holding techniques may not be possible, new half-Fourier single-shot turbo spin-echo (HASTE) imaging can be performed (Fig. 31-11).¹¹³ HASTE images can be obtained in

Figure 31-7. A, Thin-slab volumetric reconstruction (VR) of the thoracic aorta. Note the superior anatomic display of the thoracic aorta and surrounding anatomic structures. B, Thick-slab VR of the thoracic aorta. A = aorta; LA = left atrium; P = pulmonary artery.

Figure 31-8. A, Virtual endoscopic image of the aortic arch obtained with a shaded surface display (SSD) algorithm shows the origins of the great vessels. B, Virtual endoscopic image of the aortic arch using an SSD algorithm demonstrates the descending thoracic aorta. Note the origins of the intercostal arteries (*arrows*).

Figure 31-9. A, Virtual endoscopic image of the aortic arch using a volume-rendered algorithm shows the origin of the great vessels. The walls of the thoracic aorta are smoother than in the SSD algorithm images shown in Fig. 31-8. B, Virtual endoscopic image of the aortic arch using a volume-rendered algorithm displays the normal descending aorta.

Figure 31-10. A, ECG-gated axial T1-weighted image of the aortic arch (A) shows the characteristic signal void (“black blood” technique) within the transverse arch. B, ECG-gated sagittal oblique T1-weighted image of the aorta (A) shows signal void (“black blood”) within the thoracic aorta.

less than a minute with minimal loss of image quality and spatial resolution.

The standard white blood technique for evaluation of the thoracic aorta has been cine gradient-echo imaging.⁶ These sequences have been used effectively in the evaluation of the thoracic aorta and have given radiologists important information about velocity, turbulent, and slow-flow states (Fig. 31-12). Further evaluation with phase-contrast angiography has allowed accurate assessment of aortic flow velocities, valvular function, and collateral blood flow⁵⁸ in cases of aortic dissection and coarctation (Fig. 31-13). However, the long imaging times needed for

these evaluations can be limiting, and a comprehensive evaluation of the entire thoracic aorta is impractical. As with black blood techniques, effective ECG gating is still important to the success of cine GRE images.

With the advent of gadolinium-enhanced aortic imaging, a new, powerful imaging technique was established.⁹⁶ Unlike cine GRE techniques, which rely on the intrinsic signal of flowing blood, gadolinium-enhanced MR angiography takes advantage of the T1-shortening effect of gadolinium within the vascular system.⁶⁹ With the introduction of stronger and faster gradients, TR and TE values can be sufficiently shortened to maximize the signal of the gado-

Figure 31-11. A, Axial half-Fourier acquisition single-shot turbo spin echo (HASTE) MR image of the thoracic aorta shows a signal void within the aortic arch, similar to that shown in Fig. 31-10A. Compared with standard T1-weighted MR imaging, evaluation of the surrounding anatomic structures on this HASTE image is limited. B, Sagittal HASTE MR image of the thoracic aorta displays anatomic information comparable to that shown in the standard T1-weighted MR images of the aorta, as shown in Fig. 31-10B. As in A, rendering of the surrounding anatomy is limited with the HASTE sequence. A = aorta.

Figure 31-12. Axial cine gradient-recalled echo (GRE) MR image of the aortic arch shows the normal appearance of the transverse aorta. A = aorta.

linium-containing aorta in relation to the surrounding stationary tissues (Fig. 31-14).

The success of gadolinium-enhanced angiography depends on close attention to timing of the gadolinium bolus, because of significant variability in individual cardiac outputs and time to peak aortic enhancement. A number of techniques are available to maximize contrast enhancement in the ascending aorta. They include empiric timing based on the estimated cardiac output, use of a timing bolus, and automatic triggering.⁹⁵ Though beyond the scope of this chapter, newer techniques available in some centers include true fast imaging with steady-state precession (FISP) of the aorta (Fig. 31-15), which allows almost real-time imaging of the aorta. Such techniques promise to further enhance our accuracy and speed in the diagnosis of aortic disease.

Advanced CT and MRI techniques have similarly improved our evaluation of the aortic valve. ECG-gated multislice CT allows evaluation of the aortic valve in systole and diastole (Fig. 31-16), and virtual endoscopic imaging with multislice CT has enabled 3D imaging of the aortic valve, which is not possible with single-slice CT

scanners (Fig. 31-17). The superior time resolution made possible with cine MRI has also enhanced visualization of the normal aortic valve (Fig. 31-18).

Imaging Artifacts

The accurate assessment of aortic disease is complicated by a large number of imaging artifacts that can mimic important and potentially life-threatening aortic disease. With the growing use of multislice CT scanners and ECG gating, these artifacts will be significantly reduced. However, in any discussion of the role of imaging in thoracic

Figure 31-13. Phase-contrast MR image at the level of the mid-thoracic aorta shows cephalad blood flow displayed in white (black arrow), and caudad blood flow in black (white arrow).

Figure 31-14. A, Sagittal oblique gadolinium-enhanced maximum intensity projection (MIP) of the thoracic aorta in a young adult. B, Sagittal oblique gadolinium-enhanced MIP of the thoracic aorta in an elderly patient shows marked unfolding of the thoracic aortic arch. Note the smooth appearance of the ductus diverticulum.

Figure 31-15. True fast imaging with steady-state precession (FISP) cine image of the thoracic aorta. Such images provide information similar to those shown by conventional cine gradient-recalled echo images but with markedly shorter imaging times.

Figure 31-17. ECG-gated virtual endoscopic view of the aortic valve displays the sinuses of Valsalva captured in diastole.

Figure 31-16. A, ECG-gated CT scan of the aortic root clearly delineates the three aortic cusps closed in diastole (arrow). B, ECG-gated CT image of the aortic root in systole captures the opened valve cusps (arrows).

Figure 31-18. Coronal oblique image of the aortic root using a cine gradient-recalled echo (GRE) sequence delineates the three aortic cusps in diastole. Arrow denotes valve in diastole.

aortic disease, it is important to consider the wide variety of these artifacts and pitfalls.

Optimal contrast opacification is of great importance in the evaluation of aortic disease. Inadequate contrast opacification limits our evaluation of a variety of aortic diseases, particularly aortic dissection (Fig. 31-19). These limitations can be overcome with a timing bolus or the use of automated bolus-tracking techniques to optimize contrast opacification in the aorta. Even with adequate contrast opacification, there can be imaging difficulty in patients with aortic dissection, in whom there may be significant

differences in flow dynamics in the true lumen and false lumen (Fig. 31-20).⁹

Streak artifacts from adjacent vascular structures can cause artifacts that mimic aortic dissection. This appearance, most commonly seen in the ascending aorta and arch vessels, results from the high-attenuation contrast seen in the crossing brachiocephalic veins or superior vena cava (Fig. 31-21). A streak artifact can generally be distinguished from aortic dissection if one follows the artifact beyond the expected course of the aorta. Although streak artifacts can be minimized by pedal injection of the contrast agent, this route is technically more difficult and usually less acceptable to the patient. Some researchers suggest that the use of saline or diluted contrast material at the end of the contrast bolus also minimizes the streak artifacts seen from high attenuation in the brachiocephalic veins.

Adjacent anatomic structures can also mimic aortic dissections or hematoma. They include the right atrial appendage, the superior pericardial recess, and the superior intercostal vein (Figs. 31-22 and 31-23). The atelectatic lung commonly seen adjacent to the descending aorta can sometimes mimic dissection or leak (Fig. 31-24). Close examination of images superior and inferior to these images excludes dissection or hematoma.¹¹¹ Aortic pulsation artifacts (Fig. 31-25) are classic mimics of dissection flaps. Pulsation artifacts usually occur in the ascending aorta. Studies using ECG-gated electron beam computed tomography (EBCT) demonstrated significant aortic motion during the cardiac cycle and further classified their common locations. Most commonly, pulsation artifacts are seen at the 7 o'clock and 12 o'clock positions.

Aortic Arch Anomalies

It is important to recognize that the standard branching pattern of the thoracic aorta is seen in only 75% of pa-

Figure 31-19. A, Axial CT scan in a patient with suspected aortic dissection. The intravenous bolus of contrast material is early, and visualization of the thoracic aorta is inadequate. Arrow shows descending aorta. B, Axial CT scan at the level of the aortic root shows faint opacification of the aortic root with subtle delineation of ascending aortic dissection (arrow).

Figure 31-20. A, Axial multislice CT scan shows an aortic dissection flap involving the aortic arch (arrow). B, Axial scan at the level of the descending aorta shows faint opacification of the anteriorly compressed true lumen. The early injection results in inadequate visualization of the false lumen.

Figure 31-21. A, Axial CT scan above the aortic valve shows an apparent linear density mimicking dissection in the ascending aorta, secondary to a beam-hardening artifact from the presence of contrast agent in the superior vena cava (arrow). B, Axial CT scan superior to scan in A shows a normal ascending aorta with no evidence of dissection.

Figure 31-22. Axial CT scan demonstrates a suspicious soft tissue density (*arrow*) adjacent to the descending aorta.

Figure 31-23. A, Axial CT scan in a patient with known aortic aneurysm and findings suspicious for possible dissection flap involving the descending aorta (*arrow*). B, Axial CT scan superior to A shows the full course of the superior intercostal vein (*white arrow*). Note the separate medial dissection flap (*black arrow*).

Figure 31-24. Axial CT scan in a patient with a large aortic aneurysm shows abnormal, enhancing soft tissue anterior to the aneurysm (*arrow*). This soft tissue represents atelectatic lung anterior to the aneurysm.

tients.¹² The most common aortic variant is the so-called bovine arch, in which the right brachiocephalic artery and left common carotid artery have a common origin (Fig. 31-26). Although the left vertebral artery originates from the subclavian artery in most patients, it arises directly from the aortic arch in 5% to 6% of patients (Fig. 31-27); this can be an important variant in patients undergoing cerebral angiography.¹²³

Understanding congenital aortic arch anomalies requires comprehension of the embryologic double arch theory. In the standard left arch, the embryologic double arch fuses posteriorly to form the descending aorta. If the right arch is interrupted between the right subclavian artery and the descending aorta, the right subclavian and carotid arteries fuse to form the right brachiocephalic artery, resulting in the standard arch anatomy.¹¹⁸

The most common aortic arch anomaly is the left aortic

Figure 31-26. Coronal volumetric reconstruction demonstrates the common origin of the right brachiocephalic artery and the left carotid artery (*arrow*).

arch with aberrant right subclavian artery. This anomaly occurs when the right arch is interrupted between the right common carotid artery and the right subclavian artery. The right subclavian artery arises from the diverticulum of Kommerell, a persistence of the embryologic right aortic arch. In most cases, the aberrant right subclavian artery crosses posterior to the esophagus (Fig. 31-28), but it courses between the trachea and esophagus in 18% of cases, and in front of the trachea in 4%.⁶⁰ The common left aortic arch with aberrant right subclavian artery occurs in 1 in 200 patients. On a lateral radiograph, a posterior impression on the trachea can be seen. Symptoms occur at the two extremes of life in patients with this anomaly. In children, tracheal obstruction or dysphagia can occur,¹¹ whereas in adults, aneurysms of the aberrant subclavian

Figure 31-25. A, Axial CT scan shows linear pulsation artifacts in the ascending aorta that mimic aortic dissection (*arrow*). B, Axial ECG-gated CT scan obtained during diastole demonstrates resolution of these filling defects.

Figure 31-27. Axial CT shows direct origin of the vertebral artery (arrow) from the aortic arch.

artery or a prominent diverticulum of Kommerell can occur, resulting in dysphagia classically known as *dysphagia lusoria* (Figs. 31-29 through 31-31).⁷ Less common descriptions of the aberrant right subclavian artery have included superior vena cava obstruction and gastrointestinal bleeding. There are isolated case reports of thrombosis with distal embolization in patients with aberrant right subclavian artery.¹

The right aortic arch is a much less common anomaly, occurring in 0.5% of patients.⁶³ The three common anomalies of the right aortic arch are (1) right aortic arch with aberrant left subclavian artery, (2) right aortic arch with mirror image branching (see Fig. 31-22), and (3) right aortic arch with isolated left subclavian artery.³⁶ The right arch with aberrant left subclavian artery occurs in 0.6% to 0.1% (Fig. 31-32). A minority of these anomalies are associated with significant congenital heart disease, although right aortic arch is the second most common cause of vascular ring, after double aortic arch.¹³² Right aortic arch with mirror image branching is commonly associated with congenital heart disease, most often seen in patients with tetralogy of Fallot, ventricular septal defects, and truncus arteriosus. We have seen a large variety of unusual

Figure 31-28. A, Axial CT scan shows an anomalous vessel crossing behind the esophagus, consistent with aberrant right subclavian artery (arrow). Figure 31-32. A, Axial CT scan demonstrates the right aortic arch with aberrant left subclavian artery (arrow). B, Coronal multiplanar reconstruction shows that the aberrant left subclavian artery (arrow) originates from an aortic diverticulum. C, Shaded surface display from a posterior perspective shows the right aortic arch (R) with the aberrant left subclavian artery (*). Note the relationship to the trachea (T).

right aortic arch anomalies not associated with congenital heart disease (Figs. 31-33 and 31-34).

Double aortic arch, the result of persistence of the embryologic double arch, is the most common cause of a symptomatic vascular ring. The anomaly is much less commonly associated with congenital heart anomalies. In double aortic arch, the right arch is generally higher and larger than the left arch (Fig. 31-35). The descending arch is on the left side in most patients. Although this anomaly is clearly seen in asymptomatic adult patients, the size of the left aortic arch is quite variable, and the effect of a relatively atretic left arch on tracheal diameter often determines the symptoms (Fig. 31-36). Multislice CT scanning has enabled enhanced visualization of the double aortic arch in infants and neonates (Fig. 31-37).

The cervical aortic arch is an uncommon anomaly of

the aorta in which the aortic arch extends into the soft tissues of the neck. Patients with this anomaly are generally asymptomatic, but they can present with dysphagia, stridor, or a pulsatile neck mass (Fig. 31-38). Aneurysms involving a cervical aortic arch have been reported, with several cases of aneurysmal rupture. It is postulated that in patients with the anomaly and an aneurysm, embryologic development of the aortic arch was abnormal, and many patients exhibit cystic medial necrosis.⁵¹

Coarctation of the Aorta

Coarctation of the aorta is an abnormal narrowing of the descending aorta. It most commonly manifests as a focal area of narrowing distal to the left subclavian artery

Figure 31-33. A, Axial CT scan shows the right aortic arch (R). There is no evidence of an aberrant subclavian artery. B, In the same patient, an axial CT scan superior to A shows the right brachiocephalic artery (RBCA), the left common carotid artery (LCC), and the left subclavian artery (LSCA), consistent with a normal left aortic arch branching pattern.

Figure 31-34. A, Axial reconstruction from gadolinium MR angiography shows the right aortic arch and an aberrant vessel crossing posterior to the esophagus (arrow). B, Another axial reconstruction from gadolinium MR angiography shows the course of the aberrant left brachiocephalic artery (LBCA). C, Axial reconstruction shows that the aberrant vessel seen on A and B represents a left brachiocephalic artery, which divides into a left subclavian artery (LSCA) and left carotid artery (LCCA). D, Coronal mid-image shows the right aortic arch (solid arrow) with an aberrant left brachiocephalic artery (open arrow). RCCA = right common carotid artery; RSCA = right subclavian artery.

Figure 31-36. A, Axial CT scan in a patient with stridor shows the right aortic arch (R) and a small left aortic arch (L) and a small trachea in the same patient.

Figure 31-35. A, Axial CT scan shows a right-sided aortic arch (R). B, An axial CT scan at a level inferior to that of A shows a smaller left-sided aortic arch (L).

Figure 31-37. A, Axial volumetric reconstruction in a newborn with respiratory difficulty shows a double aortic arch. B, Shaded surface display in the same patient shows a double aortic arch surrounding the trachea (T). R = right aortic arch; L = left aortic arch.

Figure 31-38. A, Axial CT scan in a patient with a pulsatile neck mass shows aortic arch at the level of the clavicles (arrow). B, Volumetric reconstruction demonstrates the position of the thoracic aortic arch at the level of the clavicle (arrow).

Figure 31-39. A, Axial ECG-gated, T1-weighted MR image of the aortic arch shows narrowing of the distal aortic arch. B, Axial ECG-gated, T1-weighted image of the aortic arch at a level inferior to that of A demonstrates absence of the proximal descending aorta (arrow).

(Fig. 31-39). In the infantile form, tubular hypoplasia can affect a longer segment of the descending aorta. This anomaly is associated with bicuspid aortic valve in 75% to 85% of patients (Fig. 31-40).^{39, 126} Although coarctation of the aorta classically manifests in infants, 20% of patients are diagnosed in adolescence or adulthood. Presenting symptoms include a murmur, systemic hypertension, and differences in blood pressure between the upper and lower extremities. The incidence of cerebral aneurysms and accelerated atherosclerosis is higher in patients with coarctation of the aorta; these disorders are believed to represent sequelae of the systemic hypertension commonly seen in coarctation.

Imaging of aortic coarctation has been well characterized, and the disorder has been successfully imaged with

echocardiography, CT, and MRI (Fig. 31-41). Echocardiography and CT have been effective in evaluation of aortic coarctation, but MRI is currently regarded as the most effective method to comprehensively assess the physiologic significance of aortic narrowing (Fig. 31-42).¹¹⁵ MRI studies have shown excellent correlation with conventional angiography, whereas cine MRI and phase-contrast techniques have identified physiologically significant coarctation. Newer multislice techniques have improved the CT evaluation of aortic coarctation (Figs. 31-43 and 31-44).

Aortic Aneurysms

By definition, a true thoracic aortic aneurysm involves all components of the vessel wall. The morphologic subtypes of aneurysm are saccular (Fig. 31-45), fusiform

Figure 31-40. A, Sagittal oblique gadolinium MR angiogram of a patient with a thoracic aorta shows discrete postductal coarctation (arrow). B, Oblique cine gradient-recalled echo image demonstrates a bicuspid aortic valve (arrow).

(Fig. 31-46), dissecting, and false. In addition, acquired aneurysms can be atherosclerotic, mycotic, post-traumatic (Fig. 31-47), or secondary to cystic medial necrosis (Fig. 31-48). Although aneurysms are more common than dissections within the thoracic aorta, acute aneurysmal rupture is an infrequent occurrence (Figs. 31-49 and 31-50).^{33, 94} Initial identification of thoracic aortic aneurysms can be suspected from chest radiographs.^{50, 57} Most commonly, a mediastinal mass or enlarged segment of the aorta, often containing mural calcification, is visualized. Other findings,

such as displacement and compression of the esophagus or trachea and bronchi, may be visible on chest radiographs. Uncommon findings are erosion of the thoracic vertebrae and posterior ribs.

Contrast-enhanced CT can show that a mediastinal mass seen on chest radiographs represents an aneurysm, characterize it, and reveal its exact location. CT can also be used to ascertain whether the aneurysm affects the takeoff of the arch vessels (Fig. 31-51). In addition, CT can demonstrate the following characteristics of the aneurysm: dilatation of the aorta, calcification, intraluminal thrombi, displacement or erosion of adjacent structures, and perianeurysmal thickening and hemorrhage.^{38, 39, 133, 134} Identification of mural thrombus and calcification are common with contrast-enhanced CT, because most aortic aneurysms are secondary to arteriosclerosis. Mural thrombus, reported in up to 86% of patients, is typically crescent-shaped and circular in appearance, with the residual aortic lumen appearing smooth.^{48, 74, 129} Calcification within the wall of aortic aneurysm has been reported in 83% of patients and typically appears as discontinuous plaques and curvilinear segments.^{39, 74} Calcification within the mural thrombus can be seen in up to 17% of aortic aneurysms and can be mistaken for the displaced intimal calcification seen in aortic dissections.^{39, 47, 129}

Thoracic aortic aneurysms are most commonly located within the descending aorta at the level of the ligamentum arteriosum, just distal to the origin of the subclavian artery. They are less commonly found within the descending aorta at the level of the aortic hiatus of the diaphragm. The aortic arch is the next most common site, followed by the ascending aorta (Figs. 31-52 and 31-53).^{47, 57} In a patient with an aneurysm involving the descending aorta, the esophagus is displaced to the right, and the trachea and bronchi are displaced anteriorly. Aneurysms of the aortic arch and ascending aorta produce compression rather than displacement of adjacent mediastinal structures.⁵⁷

The presence of a thoracic aortic aneurysm should not

Figure 31-52. Axial CT scan demonstrates an aneurysm of the ascending aorta in a patient presenting with acute chest pain.

be concluded solely from the measurement of aortic circumference. The circumference of the aorta varies significantly according to the size, sex, and age of the patient and the width of the thoracic vertebral body.⁴⁹ For practical purposes, in the diagnosis of a thoracic aortic aneurysm, the descending aorta should never be larger than the ascending aorta at a given scan level, and the ratio of the coronal diameter of the ascending aorta to that of the descending aorta should be about 1.5:1.⁴⁹ The maximum diameter of the aneurysm correlates well with the incidence of rupture. For aneurysms less than 5 cm in diameter, the incidence of rupture is 2%; for aneurysms larger than 10 cm, the incidence of rupture is greater than 50%. Up to 50% of deaths from thoracic aortic aneurysms are caused

by rupture.^{33, 94} A leaking or ruptured thoracic aortic aneurysm creates extensive tissue density from mediastinal hematoma and, occasionally, a left pleural effusion (see Fig. 31-50). Rarely, contrast material can be seen beyond the confines of the aortic wall on bolus-injected, contrast-enhanced CT scans.

The advent of helical CT scanners and the use of CT angiography have made diagnosis and characterization of aortic aneurysms easier and more accurate and have also enabled highly accurate differentiation of other diseases of the aorta.^{13, 97} In contrast to conventional CT, CT angiography provides an overall picture of the aneurysm; the use of MPR, MIP, and true 3D SSD images permits very precise measurement of the maximum diameter of the aneurysm.¹³ In addition, the use of thin beam collimation and maximum vascular enhancement during a single breath-hold sequence allows the extent of the aneurysm to be delineated accurately with respect to the major aortic branches.¹⁴⁰ CT angiography also preserves the advantages of conventional CT—demonstrating extraluminal disease and the relationship of the aneurysm to adjacent organs.

Thoracic aortic aneurysms are also easily identified with MRI.^{25, 37, 72, 83, 138} MRI can identify aneurysms involving the ascending aorta, aortic arch, and the descending aorta (Fig. 31-54).^{37, 138} The technique readily depicts vascular structures because of a naturally occurring contrast between the low signal intensity of flowing blood and the higher signal intensity of the vessel walls. MRI has several advantages over CT. The first is MRI's multiplanar capability, which makes characterization of the aneurysm and determination of arch vessel involvement easier. The second is that CT requires injection of iodinated contrast medium but MRI does not; this is an important consideration in patients who either have a baseline impairment in renal function or are at risk for contrast medium-induced renal

Figure 31-53. Axial CT scan shows an aneurysm in the ascending aorta with an active leak (arrow). The patient presented with hemorrhagic pleural effusion and died the next day. A = ascending aorta.

Figure 31-55. A, Axial ECG-gated, T1-weighted MR image of the ascending aorta shows marked dilatation of the ascending aorta in a patient with Marfan's syndrome. B, Coronal cine gradient-recalled echo MR image of the aorta of the same patient demonstrates a prominent ascending aorta (A) with effacement of the sinuses of Valsalva. There is significant aortic insufficiency, demonstrated by the large area of signal loss/dephasing at the level of the aortic valve (arrow).

failure. MRI also provides information on relative blood flow that CT cannot (Fig. 31-55).³⁵ The limitations of MRI compared with CT include inferior spatial resolution, the inability to ensure that the entire region of interest is imaged in one section, a failure to detect calcifications, and difficulty monitoring critically ill patients.³⁵ In addition, patients with cardiac pacemakers and some prosthetic cardiac valves and angiographic stents are precluded from undergoing MRI examinations because of the high field strength of the MRI magnet.

Rapidly flowing blood appears on MRI as a signal void on first-echo images, emitting little or no signal, but demonstrates a relative increase in signal intensity on second-echo images. In contradistinction, thrombus within the aortic lumen, when present, demonstrates a relative decrease in signal intensity on second-echo images.^{4, 27, 133} These characteristics allow precise measurements of the diameter of thoracic aortic aneurysms and nearly exact correlation with the same measurements obtained on CT.³⁷ As stated previously, the ability to image in multiple planes with MRI allows accurate characterization of the extent of an aneurysm to determine whether it involves the origins of the arch vessels. Finally, MRI, like CT, is useful in providing information concerning the relationship between aneurysms and the surrounding mediastinal structures, and MRI has been reported to be ideal for detecting mediastinal hematoma, a secondary sign suggesting rupture of the aneurysm.⁷

Thoracic Aortic Dissection

Acute aortic dissection is a true medical emergency that must be recognized promptly and diagnosed accurately.

The mortality rate in untreated patients is reported to be approximately 25% during the first 24 hours, 70% during the first 2 weeks, and 90% after 2 weeks.^{21, 52} Dissection occurs from a tear in the wall of the aorta with subsequent hemorrhage of blood into the media, creating a second or false lumen. This false lumen is usually located between the inner one third and outer two thirds of the media, rarely involving more than half the circumference of the aorta.¹⁰¹ By far the condition most commonly predisposing to aortic dissection is systemic hypertension. Other, less common conditions are Marfan's syndrome, Ehlers-Danlos syndrome, pregnancy, syphilis and other causes of aortitis, and coarctation.¹⁰¹

The Stanford classification of aortic dissections into two types directly related to prognosis and therapy has become generally accepted.¹⁰¹ Type A dissections involve the ascending aorta, account for 60% to 70% of dissections, and usually arise within a few centimeters of the aortic valve. Without treatment, type A dissections are virtually always fatal, and death usually results from extension to and involvement of the aortic valve ring and ostia of the coronary arteries, which produces aortic valvular incompetence and left heart failure.¹⁰¹ Type B dissections involve the descending thoracic aorta, most commonly arising just distal to the origin of the left subclavian artery near the insertion of the ligamentum arteriosum. Classically, type B dissections do not carry the risk of proximal extension and are, therefore, best treated medically with blood pressure reduction. If the dissected segment of the aortic becomes aneurysmally dilated with time, however, surgical intervention may be needed.¹⁰¹

The 3-year mortality rates for both surgically and medically treated thoracic aortic dissections are approximately 21% for Stanford type A dissections and 29% for type B

Figure 31-56. A, Axial CT scan shows type A aortic dissection with the dissection flap in the aortic arch (*arrow*). B, Axial CT scan at a level inferior to that of A reveals that the dissection flap involves the ascending aorta (*top arrow*). The true lumen is compressed anteriorly (*bottom arrow*).

Figure 31-57. A, Axial noncontrast CT scan of the aorta shows the line of high attenuation (*long arrow*) in an aneurysmal ascending aorta. There is also a rim of high attenuation along the lateral aortic wall (*short arrow*). B, Axial CT scan at a level superior to that of A demonstrates medial displacement of aortic calcification (*arrow*). C, Contrast-enhanced axial CT scan shows the dissection flap of type A dissection of the thoracic aorta (*arrow*).

Figure 31–58. A, Axial CT scan shows type A dissection flap (arrow). B, Sagittal oblique multiplanar reconstruction demonstrates the dissection flap (arrow) demarcating the false lumen (F) from the posterior true lumen (T).

dissections.¹²⁴ Long-term prognosis depends on the development of complications, which mainly consist of new or progressive dissection and dilatation and subsequent rupture of the false lumen.²²

Although the findings are nonspecific, chest radiographs are frequently abnormal in patients with thoracic aortic dissections.⁵⁴ Progressive widening of or progressive changes in the configuration of the aorta on sequential radiographs are highly suspicious for dissection. Unexplained differences in sizes between the ascending and descending portions of the aorta are also suspicious. As with aortic aneurysms, the trachea and esophagus may be displaced. Signs of a left pleural effusion, an apical pleural cap, and paraspinal widening may indicate leakage from a dissection. In addition, enlargement of the cardiac silhouette or plain film evidence of acute left heart failure may be secondary to aortic insufficiency from a type A thoracic aortic dissection. Although found in only a minority of patients, the most specific plain film finding in aortic dissection is displacement of intimal calcification from the outer margin of the aorta by at least 4 to 5 mm.⁵⁴

CT has proved to be a highly reliable modality for diagnosing or excluding aortic dissection (Fig. 31–56).^{48, 57, 128} Unlike for aortic aneurysms, however, diagnosis and characterization of thoracic aortic dissection requires both non-contrast and contrast-enhanced scanning.

The diagnosis of aortic dissection can be made from noncontrast scans that demonstrate a crescentic area of increased attenuation within the wall of the aorta, a sign that has been reported to be present in 44% of cases.^{47, 137} This finding is believed to represent intramural hemorrhage from rupture of the vasa vasorum without an intimal tear.¹³⁷ Other findings have also been described on noncontrast scans. Displaced intimal calcifications are frequently encountered; however, this finding can create a problem if one is trying to differentiate between chronic thrombosed dissections and displaced intimal calcifications from aortic aneurysms with calcifications within thrombi (Fig. 31–57).^{47, 74, 129} Rarely, in severely anemic patients, the intimal flap itself can be visualized within the aortic lumen.²³

After administration of a contrast medium, diagnosis of aortic dissection is made on CT scans that demonstrate two opacified channels separated by an intimal flap.^{39, 44, 48, 70} The two lumens are reported to be visible in at least

75% of symptomatic patients with acute aortic dissection. Within the ascending aorta, the false lumen is usually anterior (Fig. 31–58), whereas in the descending aorta, it is usually posterolateral.⁷⁰ Other, ancillary findings are less sensitive but have been reported; they include differential flow through the two lumens (Fig. 31–59), an increase in the size of the aorta, and the presence of hemopericardium.⁷⁶

The standard for diagnosis of aortic dissections has long been angiography. However, numerous reports comparing the efficacy of CT with angiography in diagnosing aortic dissections have shown CT to be highly accurate. In most reports, the accuracy of CT compares favorably with that of angiography, including documented cases in which the diagnosis was made only with CT.^{87, 104, 128} However, in a small percentage of patients with acute aortic dissection, false-negative CT findings do occur.^{88, 66, 19} In addition, in a small percentage of patients with acute aortic dissection, the false channel is thrombosed and does not opacify with administration of contrast medium. This thrombosis of the false channel may represent bleeding into the wall of the aorta from rupture of the vasa vasorum without an intimal

Figure 31–59. Axial CT scan of the descending aorta shows markedly delayed clearance of contrast medium in the false lumen (arrow) in a patient with Marfan's syndrome and type B dissection.

Figure 31-60. A, Axial multislice CT scan shows type B dissection. The entry point of the dissection is clearly delineated (arrow). B, Axial multislice CT scan at a level inferior to that of A shows slower flow in the larger false lumen (arrow). C, Coronal multiplanar reconstruction clearly demonstrates the extent of dissection. Note the lack of pulsation artifact in this multislice CT scan. D, Coronal multislice CT scan with volume rendering shows that the dissection flap extends just superior to the takeoff of the right renal artery (arrow). E, Virtual endoscopic image of the descending aorta shows the dissection flap (arrow) separating the true and false lumens.

Figure 31-61. A, Sagittal oblique volume-rendered, multislice CT scan demonstrates a compressed true lumen with slow flow through the posterior false lumen (F). B, Sagittal oblique multislice CT scan shows the smaller true lumen giving rise to the celiac axis (arrow) and superior mesenteric artery.

tear. The false lumen is thrombosed more frequently, however, in subacute and chronic dissections. The overall accuracy of CT in diagnosing or excluding aortic dissection exceeds 90%, thereby ensuring its role as a primary modality in the assessment of thoracic aortic dissection.

The advent of helical CT scanners and CT angiography in particular further enhances the role of CT in the diagnosis or exclusion of thoracic aortic dissection. CT angiography can demonstrate the dissection flap more clearly than conventional CT, because scans are obtained during maximal arterial enhancement of the aorta and image reconstructions are thinner in section thickness. Therefore, the origin of the dissection flap as well as major aortic branch involvement can be evaluated in a larger proportion of patients by means of CT angiography (Figs. 31-60 and 31-61).¹³ Also, multiplanar and 3D images allow an overall view of the dissection and clarify the anatomic relationship between the dissection flap and the adjacent great vessels, similar to the multiplanar capability of MRI. These advantages were demonstrated in a report by Chung and colleagues,¹³ in which no false-positive or false-negative CT angiography findings were obtained in a series of 49 patients with suspected aortic dissection. However, unlike MRI, CT angiography has limitations in the evaluation of coronary artery involvement and aortic regurgitation.¹³ Another limitation of CT angiography is that an unopacified false lumen from a short scanning delay time with slow filling of contrast medium can be confused with a thrombosed false lumen.

MRI can generally provide a definitive diagnosis of aortic dissection by demonstrating the two lumens and the intimal flap between them, similar to the criteria for CT.^{3, 26, 35, 37} The intimal flap appears as a linear structure of intermediate signal intensity separating the true lumen

from the false lumen (Figs. 31-62 and 31-63). Flow characteristics within the two lumens can generally be demonstrated by MRI (Fig. 31-64). Characteristically, significant bright signal within what is presumed to be the false lumen is seen on second-echo sequences because of the presence of slow flow within the false lumen.^{26, 27, 37, 133} In reality, however, accurate differentiation between the true and false lumens may not be possible, because flow within the anatomic false lumen may exceed flow within the compressed residual true lumen. In addition, identification of the site of the intimal tear is most often not possible.^{37, 133} Blood within the mediastinum is readily visible on MRI, demonstrating the presence of periaortic hematoma. Also, blood within the pericardial sac can be recognized, indicating leakage from the false lumen.^{3, 26}

The accuracy of MRI for the diagnosis of aortic dissection has been well established. Radiologists with experience reading MRI sequences have approximately a 95% sensitivity and 90% specificity for detecting aortic dissection.⁶³ In addition, CT and MRI have proved comparable in the ability to identify or exclude aortic dissection; the sensitivity of MRI has been found to range from 84% to 96%, depending on the series.^{3, 35, 37, 63} Several pitfalls in interpretation of MR images of the thoracic aorta for dissection are known.^{119, 136} Fluid within the superior pericardial recess can mimic aortic dissection. Less commonly, unusual origins of the arch vessels, an unusual position of the left brachiocephalic vein, motion artifacts, and aortic plaques can all mimic dissection.

MRI also has proved value in evaluating the results of aortic repair.^{92, 135} After surgery for aortic dissection, MRI can detect either anastomatic leaks or aneurysmal dilatation distal to the graft site. The modality can also provide useful information about the status of the residual false lumen, which often remains patent after repair.

Figure 31-62. A, Axial ECG-gated, T1-weighted MR image of a type A aortic dissection shows an intermediate-signal dissection flap in the ascending aorta (arrow). B, Cine gradient-recalled echo (GRE) MR image demonstrates the dissection flap (arrow) clearly demarcated from the aortic lumen. C, Axial cine GRE MR image reveals extension of the dissection into the aortic arch and arch vessels (arrow).

Figure 31-63. Gadolinium-enhanced sagittal oblique multiplanar reconstruction shows the dissection flap and clear demarcation of the true lumen and false lumen (F). Thrombus associated with the false lumen is well delineated (arrow).

Thoracic Aortic Trauma

Acute traumatic aortic injury is responsible for 10% to 20% of fatalities resulting from high-speed deceleration trauma (passengers or pedestrians involved in motor vehicle, airplane, and boat accidents and in high falls) and crush injuries to the chest.^{20, 41, 65, 66, 90, 117, 122} Eighty percent to 90% of patients involved in high-speed deceleration accidents die before reaching the hospital. Of patients with untreated aortic injury, 30% die within 6 hours, 40% to 50% die within 24 hours, and 90% die within 4 months.⁹⁰ Chronic post-traumatic false aneurysms, or pseudoaneurysms, develop in 2% to 5% of patients with undiagnosed acute traumatic aortic injury (Figs. 31-65 and 31-66).^{30, 90, 108} Of the patients with thoracic aortic injury who reach the hospital alive, 60% to 70% survive; therefore, prompt and accurate diagnosis and surgical management are critical.⁹⁰

Signs and symptoms of traumatic deceleration injury of the thoracic aorta include chest and midscapular back pain, dyspnea, external signs of chest trauma, hypotension, upper extremity hypertension, bilateral femoral pulse deficits, and a systolic ejection murmur.⁶⁷ In general, the injury is a transverse laceration through the aortic intima, ranging in size from less than 1 mm to a completely circumferential tear; however, the adventitia is intact in roughly 60% of

Figure 31-64. A, Axial cine gradient-recalled echo (GRE) MR image shows type B dissection, with a smaller, compressed true lumen and a posterior false lumen (F). B, Sagittal oblique cine GRE image in a patient with dissection shows bright signal in anterior true lumen, consistent with faster flow (arrow). F = false lumen. Arrow denotes thrombus surrounding the false lumen.

cases, a feature that aids the development of pseudoaneurysms that delay complete rupture.⁹⁰ No portion of the circumference of the aorta is known to be more at risk to injury than any other, but noncircumferential tears are more commonly posterior in the aorta.⁹⁰

Ninety percent of thoracic aortic injuries occur within the proximal descending aorta at the level of the aortic isthmus, immediately distal to the origin of the left subclavian artery and just proximal to the site of attachment of the ligamentum arteriosum.⁴³ Thoracic aortic injury involving the ascending aorta is identified clinically in only 5%

of cases; however, at autopsy, the ascending aorta is found to be the site of injury in 20% to 25% of cases.⁴³

The mechanisms of injury, as stated before, involve high-speed deceleration and crushing forces to the chest, most commonly seen in motor vehicle and boat accidents, airplane crashes, and falls from great heights. The forces involved depend on the segment of the aorta affected. Shearing and bending forces affect the aortic isthmus.

Figure 31-65. Axial CT scan in a patient with remote history of being kicked by a horse shows a large aortic pseudoaneurysm (*) and large amount of surrounding thrombus (arrow).

Figure 31-66. Axial CT scan shows a large calcified (arrow) aortic pseudoaneurysm (F) in a patient with a remote history of a high-speed motor vehicle accident.

somewhat mobile aortic arch differs from that of the relatively fixed descending aorta. Bending stress occurs as the aorta is flexed off the left pulmonary artery and mainstem bronchus.^{10, 73, 112} One mechanism of injury within the ascending aorta is torsion, which occurs by displacement of the heart during impact and affects a region just above the aortic valve. The other mechanism involves the water-hammer effect, in which a sudden increase in intra-aortic pressure may lead to rupture of the ascending aorta into the pericardium and cardiac tamponade. Fractures of thoracic vertebral bodies are often associated with injuries involving the more distal descending aorta.^{10, 73, 112}

Chest radiography is the front-line screening test for aortic injury, and abnormal findings on chest radiographs are the most common indication for further evaluation.⁴³ The anteroposterior projection with the patient in the supine position is most commonly performed and evaluated for signs of mediastinal hematoma, an indication of significant aortic injury. However, aortic trauma is the cause of mediastinal hematoma in only 12.5% of cases.¹⁰⁹ The most sensitive findings are widening of the mediastinum (>8 cm at the arch) and irregularity or obscuring of the aortic arch margin. However, although the sensitivity of these findings for aortic injury is high (around 80%), their specificity is no more than 50%.⁹¹ The more specific signs (with specificities around 80%) include widening of the left paraspinal stripe and right-sided deviation of the trachea, esophagus, or both; however, the sensitivity for these signs is much lower.⁹¹ Chest radiographs with a normal-appearing mediastinum have been documented in patients with known aortic injury.^{14, 125} Therefore, chest radiographs are relatively insensitive in patients who have acute traumatic injury of the aorta but little or no mediastinal hemorrhage.

The low positive predictive value of chest radiography has dictated the performance of a large number of thoracic aortograms in the past. Aortograms have long been the reference standard in imaging the post-traumatic thoracic aorta, because of sensitivities approaching 100% and specificities of approximately 98%.³² The positive predictive value of chest radiographs is low in the setting of aortic trauma. When chest radiography alone is used to screen for thoracic aortic injury, only 10% to 20% of thoracic aortograms are positive for aortic or aortic branch vessel injury.^{78, 79} A more accurate and noninvasive screening test for thoracic aortic injury after blunt chest trauma is desirable.

Since its inception, CT has been investigated as a complementary examination for evaluation of traumatic aortic injury to reduce the number of negative aortograms.^{17, 31, 34, 47, 75, 80, 81, 84, 100} Mirvis and associates⁸¹ reported the clinical outcomes in 677 patients whose treatment was guided by findings on contrast-enhanced CT scans performed on a nonhelical, fourth-generation scanner. Aortography was performed when CT demonstrated either mediastinal hematoma or direct signs of vessel injury. This study reported a 90% sensitivity for CT, a 99% specificity, and a 90% positive predictive value, with no false-negative CT results. In addition, Gavant and colleagues³⁴ reported the clinical outcomes in 1518 patients who underwent CT for blunt chest trauma regardless of chest radiograph findings and whose treatment was based on the findings of contrast-

enhanced helical CT scanning. Aortography was performed if CT demonstrated either mediastinal hematoma or direct vessel injury. In this study, CT had a 100% sensitivity, an 82% specificity, and a 47% positive predictive value for direct depiction of vessel injury, and no false-negative results were obtained. These findings support the inclusion of CT in the screening for traumatic aortic injury after blunt chest trauma.

Contrast-enhanced CT can be used to evaluate both indirect (mediastinal hemorrhage) and direct signs of aortic injuries. Mediastinal hemorrhage appears as either diffuse or focal soft tissue attenuation surrounding mediastinal structures, and the location of the blood has diagnostic significance. Hemorrhage in the vicinity of and surrounding the aorta and other vascular structures is more suggestive of vascular injury.¹⁸ Direct signs of aortic injury are polypoid (clot) or linear (intimal flap) intraluminal areas of low attenuation, pseudoaneurysm, irregularity of the aortic wall, pseudocoarctation, intramural hematoma, dissection, and frank extravasation of contrast material (Fig. 31-67).^{49, 80, 84}

Certain pitfalls make interpretation of CT scans difficult for thoracic aortic injury.^{31, 45, 98} They include motion artifacts, partial volume averaging, and support devices. In addition, atelectatic lung (especially in the apical-posterior segment of the left upper lobe and superior segment of the left lower lobe) can mimic hemorrhage adjacent to the aorta. The thymus, pericardial recess, and unopacified vessels can also mimic blood. Knowledge of these common artifacts and mimics of mediastinal blood makes interpretation of scans more accurate.

MRI is a valuable tool for evaluation of the aorta in most trauma patients. Imaging time, incompatibility of MRI equipment with monitoring devices, and inaccessibility of the patient during the examination preclude the routine use and widespread acceptance of MRI in the evaluation of acute thoracic aortic injury.^{15, 43, 77} Despite these limitations, several case reports have described MRI's ability to demonstrate acute thoracic aortic injury in awake, alert, and stable patients with no other injuries (Fig. 31-68).^{15, 53} A study by Fattori and colleagues²⁸ concluded that MRI was accurate and reproducible for acute thoracic aortic injury compared with CT, angiography, or both in 24 patients with acute blunt chest trauma who did not undergo surgery. They also concluded that MRI provided complete anatomic data for assessing the severity of the aortic injury. It is the ideal modality for monitoring acute thoracic aortic injury prior to surgical repair.

Intramural Hematoma

The concept of the intramural hematoma was first described by Krukenberg. It describes blood within the wall of the aorta without identifiable intimal tear. Pathologically, intramural hemorrhage is defined as rupture of the vasa vasorum and propagation of subintimal hemorrhage, often secondary to a penetrating atherosclerotic ulcer. Isolated case reports have described spontaneous progression to aortic dissection.⁶⁸ Clinically, the signs and symptoms are often indistinguishable from those of dissection. Intramural hematoma progresses either by outward rupture of the aortic wall or by inward extension and formation of an intimal flap.¹⁰²

Figure 31-67. A, Axial CT scan in a patient who experienced a high-speed motor vehicle accident shows evidence of acute post-traumatic pseudoaneurysm (arrow). B, Sagittal multiplanar reconstruction demonstrates a focal pseudoaneurysm in the proximal descending aorta (asterisk). Note the acute angle of the pseudoaneurysm with the adjacent aorta, a feature that distinguishes it from a ductus diverticulum. C, Virtual endoscopic image demonstrates the focal nature of the post-traumatic pseudoaneurysm. P = pseudoaneurysm; A = native aortic lumen.

Figure 31-68. Gadolinium MR angiograph shows discrete post-traumatic pseudoaneurysm (thin arrow) with associated intimal flap (thick arrow) in a young man several months after a high-speed motor vehicle accident.

Distribution of intramural hematomas is equally divided between the ascending and descending portions of the aorta, with a small number occurring in the transverse arch. Studies have shown that the prognosis for patients with such hematomas is very similar to that for patients with aortic dissection. Intramural hematomas of the ascending aorta often progress to dissection, whereas those of the descending aorta progress less often to dissection or aneurysm formation (Fig. 31-69).⁸⁵ Our experience suggests that progression to aneurysm formation is more common in patients with descending intramural hematomas and that such patients should be followed more closely than patients with aneurysms of the descending aorta (Fig. 31-70).

The majority of intramural hematomas are the result of penetrating atherosclerotic ulcers (Fig. 31-71). First described as a distinct entity in the literature in 1986 by Stanson and associates,¹²⁰ atherosclerotic ulcers are defined by an abnormal outpouching of the contrast medium beyond the expected course of the aortic lumen.⁷¹ Patients present clinically with chest or back pain, and the symptoms commonly mimic aortic dissection. Like dissection, intimal calcifications are displaced medially by the penetrating ulcer. There is an associated subintimal hematoma, and the spiraling flap seen in aortic dissection is absent. Penetrating atherosclerotic ulcers are generally located in the distal two thirds of the descending aorta. The penetrating ulcer can usually be distinguished from aortic dissec-

Figure 31-69. A, Axial noncontrast CT scan shows a rim of high attenuation of the aortic wall (arrow) in a patient with acute chest pain. B, Axial CT scan after administration of a contrast agent demonstrates diffuse periaortic soft tissue with high attenuation (arrow), a feature consistent with acute intramural hematoma.

tion because of the more focal, irregular nature of the defect, and the dissection flap is often smooth and well defined (Fig. 31-72).

There is controversy about the appropriate treatment of patients with penetrating ulcers. Many patients are first treated medically with antihypertensive medications. Patients for whom such treatment relieves pain and in whom the ulcer has a stable appearance on follow-up imaging can continue to be treated nonsurgically. In patients with continued pain or enlargement of the ulcerated area on follow-up imaging, surgical intervention is warranted (Fig. 31-73). Surgical treatment can be quite different; patients with atherosclerotic ulcers often require a longer interposition graft, whereas those with dissections need a shorter graft at the site of the intimal tear.¹⁶

Atheroembolic Disease of the Aorta

Appreciation of the importance of aortic atherosclerosis has grown with our increasingly aggressive treatment of

cerebrovascular disease. Until the 1990s, close to 40% of cerebrovascular events were classified as “cryptogenic.” With the advent of transesophageal echocardiography, the importance of atheroembolic disease of the aorta has become more recognized. Retrospective studies showed that in patients with cerebrovascular accidents, the incidence of aortic atheromas was 20% to 27%,¹³⁰ compared with 5% in control subjects. Research showed that aortic plaque size determined risk, with plaques larger than 4 mm resulting in an odds ratio of 13.8 for the incidence of cerebrovascular events (Figs. 31-74 and 31-75). The absence of calcification was a poor prognostic feature, indicating those plaques most likely to embolize. Reports now suggest that CT and MRI may be complementary modalities in the detection of these atheroemboli, particularly in areas of the aortic arch where the tracheal air column limits evaluation with transesophageal echocardiography.¹²⁷ Multislice CT will continue to improve the sensitivity of CT scanning for the diagnosis of atheroembolic disease. Newer imaging techniques will prove to be of added benefit in the diagnosis and characterization of these vulnerable plaques.

Figure 31-70. A, Axial CT scan in a patient with acute back pain. There is a large amount of high-attenuation periaortic soft tissue (arrow), a feature consistent with intramural hematoma. B, Axial CT scan taken 2 months later shows a rapid increase in the diameter of the descending aorta (A).

Figure 31-71. A, Axial CT scan in a patient with acute back pain and suspected aortic dissection. Note the focal ulceration in the descending aorta (*arrow*). B, Axial CT scan at the level of the aortic arch shows high-attenuation periaortic soft tissue (*arrow*), a finding consistent with intramural hematoma. C, Axial CT scan obtained 2 months later demonstrates a marked increase in the diameter of the descending aorta.

Figure 31-72. A, Axial CT scan in an elderly woman with acute back pain. There is a collection of contrast material medial to the descending aorta (*thick arrow*) that has a narrow but discrete communication with the aortic lumen (*thin arrow*). B, Sagittal oblique maximum intensity projection from gadolinium MR angiography delineates the focal atherosclerotic ulcer and its relationship with the aortic lumen (*arrow*).

Figure 31-73. A, Axial noncontrast CT scan in an elderly patient who presented with a mediastinal mass contiguous with the descending aorta (P). Note the discontinuity of aortic calcification at this level. A = native aortic lumen. B, Sagittal maximum intensity projection from gadolinium MR angiography demonstrates an eccentric contrast collection (*black arrow*) with a large amount of surrounding thrombus (*white arrow*). C, Sagittal MPR image shows severe atherosclerotic ulceration of the descending aorta. P = pseudoaneurysm.

Figure 31-74. A, Sagittal oblique multiplanar reconstruction from multislice CT scan in an elderly woman with a history of embolic strokes. Note the large atheroma protruding into the aortic lumen (arrow). B, Virtual endoscopic image shows large protruding atheroma (*) within the transverse arch.

Figure 31-75. A, Sagittal oblique multiplanar reconstruction from multislice CT scan in a patient with a splenic infarct and arm weakness. There is a polypoid atheroma within the transverse arch (arrow). B, Virtual endoscopic image of the aortic arch shows a pedunculated atheroma (arrow) within the arch.

Aortitis

Inflammatory diseases of the aorta, though rare, have been well characterized in the imaging literature. Takayasu's arteritis is the best described of these disease processes. It is generally classified into four types on the basis of its anatomic location. Type 1 describes disease in the aortic arch, type 2 involves the abdominal aorta, type 3 the entire aorta, and type 4 the pulmonary arteries. In Takayasu's arteritis of the thoracic aorta, disease usually manifests as stenosis, occlusion, and aneurysm formation (Fig. 31-76). Some reports have described the superiority of CT over aortography. Although stenoses and aneurysmal changes are evaluated equivalently by the two modalities, mural changes are better evaluated with CT. In patients with suspected Takayasu's arteritis, initial noncontrast studies will show a high-attenuation aortic wall. Both aortic wall enhancement with contrast agent and delayed enhancement have been described.⁸⁹ These findings are important to define, as they may predate clinical symptoms and laboratory data. Documentation of improvement in aortic wall thickening after steroid therapy has been described.⁴⁶

Giant cell arteritis is a vasculitis that often affects the thoracic aorta. On pathologic examination, active granulomatous inflammation with multinucleated giant cells are

found in the aortic wall. Although the aortic arch vessels can be involved with stenoses, involvement of the aorta results in aneurysm formation. In a population-based study, 10% of patients with giant cell arteritis experienced aortic aneurysms (Fig. 31-77). These patients may also have aortic valve insufficiency.

Other forms of aortitis affecting the thoracic aorta are granulomatous aortitis (Fig. 31-78), lymphoplasmacytic aortitis (Fig. 31-79),²⁹ and aortitis associated with antineutrophil cytoplasmic antibody (ANCA).⁸⁶ These unusual forms of aortitis are often associated with aneurysm formation, but dissection has also been reported.

The Postoperative Aorta

With the increasing age of the population and the greater prevalence of atherosclerotic disease, larger numbers of aging patients are undergoing cardiothoracic surgery. Postoperative complications in the aorta are an uncommon cause of postoperative morbidity and mortality but they should be considered in patients who present with pain or in whom imaging studies show mediastinal widening. Importantly, many of these changes can occur years after the original operation. During surgery of the heart and

Figure 31-76. A, Axial multiplanar reconstruction (MPR) from gadolinium MR angiography of the thoracic aorta in a patient previously diagnosed with Takayasu's arteritis who has shown evidence of an acute stroke. The aortic root and main pulmonary artery are enlarged. B, Coronal MPR from gadolinium MR angiography demonstrates circumferential soft tissue thickening of the aortic arch (arrow). C, Sagittal MPR shows prominence of the ascending aorta (A) as well as occlusion of a markedly narrowed left subclavian artery (arrow). D, Coronal MPR shows dilatation of a segment of the main pulmonary artery, a finding consistent with pulmonary artery involvement in Takayasu's arteritis. P = main pulmonary artery.

Figure 31-77. A, Axial CT scan in a young man in whom a chest radiograph showed an aortic prominence. Note the enlarged aortic root (arrow) with asymmetrical enlargement of the noncoronary cusp (*). B, Virtual endoscopic image shows normal appearance of the left (L) and right (R) coronary cusps and asymmetrical enlargement of the noncoronary cusp (N).

Figure 31-78. A, Axial half-Fourier acquisition single-shot turbo spin echo (HASTE) MR image in a young man in whom a chest radiograph showed mediastinal widening. This image reveals enlargement of the aortic root (A). B, Coronal cine gradient-recalled echo MR image at the level of the aortic valve during early diastole shows a linear focus of signal dephasing, a finding consistent with aortic insufficiency (arrow).

Figure 31-79. A, Sagittal oblique multiplanar reconstruction from CT scanning in an older woman who presented with chest pain. There is aneurysmal dilatation of the descending thoracic aorta (A) with marked irregularity or ulceration (arrow). B, Virtual endoscopic image of the descending aorta shows extensive ulceration (arrows).

Figure 31-80. A, Axial CT scan with volumetric rendering shows lobulated soft tissue (arrow) extending from the aortic root (A). B, Coronal volume-rendering image shows pseudoaneurysm (A) arising from the aortic root (arrow).

Figure 31-81. Sagittal multiplanar reconstruction from gadolinium MR angiography shows a large pseudoaneurysm (*) arising from the ascending aorta at the site of prior aortic cannulation.

Figure 31-82. Sagittal oblique multiplanar reconstruction from gadolinium MR angiography demonstrates a lobulated aneurysm (arrow) arising from the ascending aorta.

great vessels, the aorta is cannulated, coronary artery grafts are placed, and, in aortic valve repair, an aortotomy is performed above the valve. These areas are all sites of potential aneurysm formation (Figs. 31–80 through 31–82).⁶² Postoperative pseudoaneurysms and leaks are not uncommon after repair of aortic dissection or aneurysm and should always be considered in any postoperative patient presenting with new symptoms or a mass in the chest or mediastinum. In a large series of patients followed after aortic transposition grafts, 20% of patients required reoperation for periprosthetic pseudoaneurysms. All of the patients with pseudoaneurysms were asymptomatic. The authors of the study proposed serial evaluations in these high-risk patients to better evaluate postoperative complications.

Computed Tomography of the Heart and Pericardium

Lynn S. Broderick

Echocardiography is usually the first choice for imaging the heart, although computed tomography (CT) scanning is a preferred method of evaluating the pericardium. In the past, CT was not routinely used for evaluation of the heart. This is primarily because, with the exception of electron beam CT scanners, the scan times were not fast enough to image the heart without cardiac motion. The development of multidetector scanners, coupled with the ability to scan with prospective or retrospective electrocardiography (ECG) gating, will very likely result in increased interest in cardiac imaging by CT.

Mochizuki and associates have reported the use of ECG-gated spiral CT to create two-dimensional (2D) and three-dimensional (3D) CT ventriculography, allowing assessment of left ventricular volumes.⁶⁸ Studies are currently under way to determine the usefulness of CT angiography in evaluating the coronary arteries.⁵² Even when CT scanning is performed to evaluate other structures, much information can be obtained by careful assessment of the heart and pericardium.

Anatomy

The anatomy of the heart is often well displayed on CT scans of the chest, even in the presence of motion artifact. The most important motion artifact affecting the heart is one that can simulate aortic dissection.^{22, 36, 69} Cardiac motion is responsible for the movement of the aortic root, resulting in curvilinear artifacts that may mimic an intimal flap. The curvilinear artifacts are typically located in a left anterior and right posterior location (Fig. 32-1).^{36, 92} Multiplanar reformatted images may show a serrated appearance of the aortic wall, confirming that the curvilinear density is artifactual.⁹² Knowledge of the typical appearance and location prevents misdiagnosis.

Basic cardiac anatomy can be displayed even with conventional CT scanners. The cardiac chambers, great vessels, and veins are readily identified. With faster scanning times, other finer structures, such as papillary muscles, chordae tendineae, and valve leaflets, can also be identified (Fig. 32-2).

The coronary arteries are easily visualized. The main coronary artery arises from the left aortic cusp and courses

approximately 1 cm before giving off the left anterior descending and circumflex arteries. The right coronary artery arises from the right aortic cusp and is more caudally located than the left main coronary artery. Some structures, such as the pericardiophrenic vein, are not routinely visualized. However, knowledge of their location is useful when they enlarge as a route of collateral circulation (Figs. 32-3 and 32-4).

Evaluation of the Cardiac Chambers

Knowledge of chest radiographic findings of valvular heart disease can be extrapolated to use in interpreting

Figure 32-1. Motion artifact. Contrast-enhanced axial CT image shows apparent intimal flap (arrow) at the level of the aortic root. This appearance is caused by cardiac motion during scan acquisition. It can be recognized by its characteristic location at the aortic root. It is usually found in a left anterior or right posterior location.

Figure 32-2. Normal anatomy. Axial contrast-enhanced CT images from the level of the pulmonary arteries (A) to the level of the inferior aspect of the heart (D) display normal cardiac anatomy.

A, CT image obtained at the level of the pulmonary arteries. A, ascending aorta; D, descending aorta; L, left pulmonary artery; P, main pulmonary artery; R, right pulmonary artery; S, superior vena cava.

B, More inferior CT image demonstrates the hyperarterial left mainstem bronchus (asterisk). A, ascending aorta; D, descending aorta; P, main pulmonary artery; R, right pulmonary artery; S, superior vena cava.

C, CT image at level of the right and left superior pulmonary veins (arrows) and right and left atrial appendages (open arrows). Linear densities within the right ventricular/pulmonary artery outflow tract probably represent the valve leaflets (arrowheads). L, superior aspect of left atrium; A, ascending aorta.

D, CT image at level of origin of left main coronary artery (arrow). Calcification is present within the left anterior descending artery (arrowheads). A, ascending aorta; LA, left atrium; LS, left superior pulmonary vein; RA, right atrium; RV, right ventricular outflow tract, also known as the infundibulum; S, superior vena cava.

Figure 32-2 (Continued).

E, CT image at level of origin of circumflex artery (arrow) arising from the left main coronary artery. The normal prominence of the muscle can be visualized between the left superior pulmonary vein posteriorly and the left atrial appendage anteriorly (curved arrow). A, ascending aorta; D, descending aorta; LA, left atrium; RA, right atrium; RV, right ventricular outflow tract; S, superior vena cava.

F, CT image at the level of the right and left inferior pulmonary veins (arrows) and origin of the right coronary artery (curved arrow). The left anterior descending (open arrow) and circumflex (double arrow) arteries are also visible. LV, left ventricular myocardium; RA, right atrium; RV, right ventricular outflow tract. Portions of the aortic valve are visible (arrowhead).

G, CT image at the level of the mitral valve (arrowheads). The aortic valve leaflets are also visible (curved arrows). The mitral and aortic valves are not separated by myocardium, an indicator that this is the morphologic left ventricle. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; S, interventricular septum.

H, More inferior CT image shows the moderator band extending from the interventricular septum to the anterior free wall of the right ventricle (curved arrow). In the left ventricle, the chordae tendineae (arrowhead) can be seen extending from the papillary muscle (P) to the mitral valve leaflet (arrow). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 32-2. (Continued).

I, CT image at level of the coronary sinus (arrow), just before it enters the right atrium (RA). Note the papillary muscle (P) within the left ventricle.

J, CT image showing the posterior course of the right coronary artery (arrows) in the atrioventricular groove. M, inferior myocardium of the left ventricle; RV, right ventricle.

chest CT scans. The actual valvular structures are often not visualized. This is particularly true for the tricuspid and pulmonic valves. However, portions of the mitral and aortic valves can be identified on routine contrast-enhanced CT scans (see Fig. 32-2). Evidence of chamber enlargement and hypertrophy can also be identified on CT images. The

diseased valve can be stenotic or regurgitant, or there may be combined stenosis and regurgitation.

The cardiac chamber, which is proximal to a stenotic valve, must work against an increased pressure load. This results in hypertrophy and dilatation of the chamber. The chamber distal to the stenotic valve is unaffected. When the valve is regurgitant, the proximal chamber experiences an increased volume load because it receives additional blood through the regurgitant valve. This results in dilatation of the chamber. Because this increased blood volume is then pumped through the valve, the receiving chamber also experiences an increased volume load, resulting in dilatation.

Figure 32-3. Enlarged pericardiophrenic vein. Axial CT with intravenous contrast medium shows marked distention of the pericardiophrenic vein (arrow), which is acting as a collateral in this patient with SVC obstruction secondary to fibrosing mediastinitis. The distended azygos vein (open arrow) is also providing collateral circulation. DA, descending aorta; LV, left ventricle; RV, right ventricle.

Aortic Valve Disease

Aortic stenosis can occur secondary to the presence of a congenital bicuspid aortic valve, rheumatic heart disease, or age-related degeneration of the aortic valve. The bicuspid valve is the most common congenital heart defect and has a prevalence of 4 in 1000 live births. There is a 4:1 male-to-female ratio.⁵⁸ Patients with bicuspid aortic valve are at risk for development of aortic stenosis, bacterial endocarditis, and aortic regurgitation.

In the adult form of aortic stenosis secondary to a bicuspid aortic valve, the valve initially functions normally. The valve leaflets are continually traumatized by turbulent blood flow through the bicuspid valve and eventually become fibrotic and calcified, leading to stenosis.⁵⁶ Patients with bicuspid aortic valve tend to present with symptoms of aortic stenosis at an earlier age than do patients with degenerative aortic stenosis.

Degenerative aortic stenosis is a slowly progressive dis-

Figure 32-4. Enlarged pericardiophrenic vein. **A**, Axial CT with intravenous contrast medium shows marked distention of the pericardiophrenic vein (arrow). DA, descending aorta; LV, left ventricle; RV, right ventricle. The open arrow points to the azygos vein, and the arrowhead to the coronary sinus. **B**, More caudal image demonstrates gastric varices (arrows) as the cause of the distention of the pericardiophrenic vein.

order that affects patients 65 years of age or older. It is more common in women, and it is the most common cause of aortic stenosis in older adults. Aortic stenosis may also occur as a manifestation of rheumatic heart disease. However, patients with rheumatic aortic valvular disease usually have a combination of aortic stenosis and regurgitation and the mitral valve is also usually involved. Aortic stenosis secondary to rheumatic heart disease is more common in men than in women.

Calcification of the aortic valve can be detected on CT images. In younger patients, calcification of the aortic valve should raise the question of aortic stenosis.¹¹⁴ Calcification of the aortic valve in patients older than 65 years of age may be degenerative, and the patient may have no detectable aortic stenosis or may have only mild or moderate aortic stenosis.⁵⁷ In this older patient group, the greater the amount of calcification within the valve, the more likely the patient has aortic stenosis (Fig. 32-5).

Figure 32-5. Degenerative aortic stenosis in a 73-year-old woman. Axial contrast-enhanced CT images show (A) calcification of the aortic valve (arrowheads) and (B) dilatation of the ascending aorta. Note the thickened myocardium of the left ventricle. AA, ascending aorta; DA, descending aorta; LA, left atrium; LV, left ventricle; RPA, right pulmonary artery; S, superior vena cava.

Figure 32-6. Left ventricular hypertrophy in a patient with systemic hypertension, aortic stenosis, and aortic regurgitation. Axial contrast-enhanced CT image shows the markedly thickened left ventricular myocardium (M). The aortic valve is not calcified.

CT is also useful in depicting sequelae of aortic stenosis. Hypertrophy of the left ventricular myocardium can be detected (Fig. 32-6).⁸⁶ Poststenotic dilatation of the ascending aorta is thought to result from the increased turbulence caused by the jet of blood coursing through the stenotic valve. Cystic medial degeneration has been described as occurring in 11% of patients with aortic stenosis secondary to bicuspid aortic valve, which may also play a role in aortic dilatation.⁸⁸ Other conditions associated with bicuspid aortic valve include mitral valve prolapse, aortic coarctation, and aortic dissection.^{85, 88}

Aortic regurgitation results in volume overload of the left ventricle, which responds by dilating. Because the ascending aorta also receives an increased volume of blood with each left ventricular contraction, it also dilates.⁸⁶ In patients with aortic regurgitation, this combination of left ventricular dilatation and enlargement of the ascending aorta can be recognized on CT images (Fig. 32-7).

Mitral Valve Disease

Rheumatic heart disease, which causes the mitral valve leaflets to become thickened and calcified, is the most common cause of mitral stenosis.^{58, 86} Because involvement of the chordae tendineae causes tethering, the mitral valve is often regurgitant as well as stenotic. Pure mitral stenosis results in left atrial enlargement (Fig. 32-8).⁸⁶ The left ventricle is not enlarged unless there is also mitral regurgitation. Calcification of the mitral valve can be seen in patients with rheumatic mitral valve disease; however, it may also be seen in elderly patients in conjunction with mitral annulus calcification.¹¹⁴

Rheumatic heart disease is also the most common cause of mitral regurgitation. Other causes include abnormal pap-

Figure 32-7. Aortic regurgitation. Coronal multiplanar reformatting image from spiral CT following intravenous contrast medium. There is dilatation of the left ventricle (LV) and aneurysmal dilatation of the ascending aorta (AA), typical findings in patients with aortic regurgitation.

illary muscle function and endocarditis.⁵⁸ Mitral regurgitation causes volume overload of the left atrium and ventricle. When chronic, the regurgitation results in dilatation of both the left atrium and the ventricle.⁸⁶ The left atrium is usually more dilated in patients with mitral regurgitation than in patients with pure mitral stenosis.

The mitral annulus may calcify with age. It is easily recognized on chest radiographs as a C-shaped calcific density at the expected location of the mitral valve. Although it has been thought to be a clinically insignificant finding, some believe it to be related to atherosclerotic disease.¹⁰³ CT readily depicts calcification of the mitral annulus (Fig. 32-9). It may be difficult to distinguish between calcification of the valve itself and calcification of the mitral annulus. Calcification of the mitral annulus may also hamper detection of calcification within the circumflex artery.

Tricuspid Valve Disease

Tricuspid stenosis may result as a manifestation of rheumatic heart disease, in which case the mitral valve is usually affected as well.⁵⁸ Less common causes of tricuspid stenosis include lupus erythematosus and carcinoid syndrome. Tricuspid stenosis results in dilatation of the right atrium with a normal-sized right ventricle.

Tricuspid regurgitation may occur as a result of right ventricular enlargement stretching the tricuspid annulus. Carcinoid syndrome, papillary muscle dysfunction, and bacterial endocarditis may also cause tricuspid regurgita-

Figure 32-8. Mitral stenosis secondary to rheumatic heart disease. Axial CT with intravenous contrast medium shows (A) enlargement of the left atrium (LA) with (B) enlargement of the left atrial appendage (asterisk).

tion. The increased volume of blood through the regurgitant valve results in dilatation of both the right atrium and the right ventricle (Fig. 32-10). When intravenous (IV) contrast medium is used, the more densely contrasted blood within the right atrium may reflux into the hepatic veins. Reflux of contrast material into the hepatic veins may also be seen in patients with right heart failure.

Figure 32-9. Mitral annulus calcification. Axial contrast-enhanced CT image shows calcification of the mitral annulus (open arrow), which was also identified on chest radiograph. Calcification within the mitral annulus may be difficult to differentiate from calcium in the circumflex coronary artery. A small amount of calcification can be visualized within the aortic valve (arrow). The patient did not have evidence of aortic stenosis. D, descending aorta; E, right pleural effusion; LA, left atrium; LV, left ventricle; RV, right ventricle. The arrowhead points to the mitral valve leaflet.

Pulmonary Valve Disease

Pulmonary valve stenosis can be recognized on CT scans when there is dilatation of the main and left pulmonary arteries, which results from the poststenotic turbulent jet of blood.

Figure 32-10. Mitral stenosis and tricuspid regurgitation. There is dystrophic calcification of the wall of the left atrium (arrow) in this patient with long-standing mitral stenosis who has undergone mitral valve replacement (open arrow). The patient also had tricuspid regurgitation resulting in marked enlargement of the right atrium (RA) and right ventricle (RV). A pacemaker is also present (arrowheads).

Other Causes of Hypertrophy and Chamber Enlargement

The left ventricle may be dilated as a result of ischemic heart disease or cardiomyopathy. Dilatation of cardiac chambers can also be seen in patients with cardiac shunts (Fig. 32-11).

Left ventricular hypertrophy may be seen in patients with aortic stenosis, systemic hypertension (see Figs. 32-5 and 32-6), or hypertrophic cardiomyopathy. Right ventricular hypertrophy may be seen in patients with pulmonary arterial hypertension or outflow obstruction (Fig. 32-12).

Coronary Artery Disease

Postmortem examinations have demonstrated the presence of atheroma whenever coronary artery calcification is present.^{14, 83} Accordingly, several methods have been used to screen patients for calcified coronary arteries. Although calcified arteries can be detected on chest radiographs and on fluoroscopy, these methods are limited in their sensitivity because of the superimposition of overlying structures. Guthaner and coworkers reported the detection of coronary artery calcification by CT in 1979, but it was not until the last decade that CT has been evaluated as a possible screening test.⁴⁴

Several studies have compared the calcification of coronary arteries detected by conventional CT with angiographically detected atheromatous disease.^{62, 83} Masuda and coauthors⁶² performed conventional CT scans (10-mm slice thickness) on 161 patients and identified coronary artery calcification in 108 patients, 90% of whom showed significant vessel narrowing on an angiogram. In addition, 80% of patients with significant lesions on angiography demonstrated calcification on CT scan.

Figure 32-11. Atrial septal defect. Axial CT with intravenous contrast medium shows marked enlargement of both the right atrium (RA) and the right ventricle (RV) in this patient with atrial septal defect documented by echocardiography.

Figure 32-12. Right ventricular hypertrophy in a patient with pulmonary arterial hypertension secondary to chronic obstructive pulmonary disease. Axial contrast-enhanced CT image shows marked thickening of the free wall of the right ventricle (arrowheads), which is as thick as the interventricular septum (open arrow). P, right ventricular papillary muscle. Curved arrows point to the tricuspid valve.

Tamiya and coworkers studied 143 patients with 10-mm-thick conventional CT scans and correlated them with angiography. They found that a positive CT scan detecting coronary artery calcification had a 79% sensitivity and an 80% specificity when compared with significant coronary artery stenosis on angiograms.¹⁰²

Agatson and associates³ evaluated 584 patients with electron beam CT scans for detecting and quantifying coronary artery calcifications using a 3-mm-slice thickness. They defined calcification as densities in the anatomic location of the coronary arteries greater than or equal to 130 Hounsfield units (HU) and with an area of greater than or equal to 1 square millimeter. They scored each lesion based on the maximum density, as follows:

- 1 = 130–199 HU
- 2 = 200–299 HU
- 3 = 300–399 HU
- 4 = >400 HU

A total score was obtained by adding the scores from all of the slices. Of the 584 patients, 109 had coronary artery disease documented either by angiogram or by a positive history of myocardial infarction. For the other patients, exercise tests or angiographic findings were negative, or these patients were clinically asymptomatic. In the groups with documented coronary artery disease, 96% had coronary artery calcification scores greater than 0. The majority of patients with positive CT scans had calcifications involving the proximal arteries.

Breen's group¹⁵ studied 100 patients undergoing elective angiography with electron beam CT scanning. A scoring system identical to that used in Agatson's study³ was used,

and calcification was identified as two or more adjacent pixels measuring 130 HU or more. The area and peak CT numbers were also measured. Individual scores were summed for each major vessel. Angiographically depicted stenoses were visually assessed and considered to be "mild" if the narrowing was less than 50% and "significant" if it was greater than or equal to 50% in one or

more major branches. Seventy-one patients had positive angiograms, and 75 patients demonstrated calcifications. Of the 47 patients with significant stenoses, all had coronary artery calcifications. The sensitivity of the electron beam CT for detecting patients with a positive angiogram was 95%, and the specificity was 72%. No patients with negative CT scans had significant disease on angiography.

Figure 32-13. Axial CT images using retrospective electrocardiographic gating for calcium scoring. *A*, Calcification (arrow) is noted at the junction of the left main (open arrow) and left anterior descending (LAD) (arrowhead) coronary arteries. *B*, More caudal image shows further calcification of the LAD (arrow) and calcification in the inferior aspect of the left main artery (arrowhead). *C*, More caudal image shows the origin of the right coronary artery (open arrow) without calcification. *D*, More caudal image shows calcification (arrowhead) of the right coronary artery as it courses through the atrioventricular groove. The LAD (curved arrow) and circumflex artery (arrow) are not calcified at this level.

Helical CT can depict coronary artery calcification. Because of the longer acquisition time, some motion degradation of the images occurs, particularly if cardiac gating is not used. This may result in "blurring" of the calcification. Two studies were performed to quantify coronary artery calcification, with dual-slice spiral CT comparing the results with angiography. The sensitivity and specificity of these two studies were 88% to 92% and 52% to 72%, respectively.^{16, 94} Note that ECG gating was not used in either study.

Since the publication of these two studies, retrospective cardiac gating has been applied to spiral CT and found to reduce cardiac motion artifact.¹¹³ The major manufacturers of CT equipment have now added cardiac gating to their scanners. Carr and colleagues found that calcium scores obtained with retrospective cardiac gating and a subsecond helical CT scanner correlate well with calcium scores obtained from electron beam CT scanners.²⁶ Becker and co-workers found that calcium scores using a single-slice CT with prospective ECG gating also correlated well with electron beam CT calcium scores.¹¹

Most studies evaluating coronary artery calcium have used the Agatston method of scoring, although other methods of scoring exist. Several authors have found improved reproducibility with alternate scoring methods, including volume-based and mass-based methods as well as use of the Agatston method with average instead of peak density values.^{24, 95, 117}

Detection of coronary artery calcium indicates that atherosclerotic disease is present, and the more calcium found, the greater the amount of atherosclerosis (Fig. 32-13). However, the amount of calcium underestimates the true extent of atherosclerotic disease and it does not predict the site of areas of stenosis. Rumberger and colleagues published their criteria for patient selection and guidelines for intervention based on calcium scores.⁸⁷ Controversy still exists over which patients should undergo the test. Further studies evaluating clinical outcomes with calcium scores need to be performed.

CT may also detect the sequelae of coronary atherosclerotic disease. Evidence of previous myocardial infarction can be visualized on CT images of the heart, either as an area of thinned myocardium (Fig. 32-14) or as an area of dystrophic calcification (Fig. 32-15) in the infarcted area.

True ventricular aneurysms occur in approximately 10% of patients with a history of myocardial infarction.¹ Bulging of the thinned or calcified myocardium may be seen, consistent with a true aneurysm (see Fig. 32-14). The wall of a true aneurysm is made up of the myocardial scar and the overlying epicardium. It typically has a broad neck, since it is a continuation of the left ventricular cavity. A true aneurysm can gradually expand over time; however, rupture is rare.¹⁰⁰ Rupture of the myocardium usually results in hemopericardium and cardiac tamponade. When the rupture is contained by the pericardium, a pseudoaneurysm results.

Ventricular pseudoaneurysms are thought to occur in the presence of pericardial adhesions,⁴⁸ due either to a previous myocardial infarction with associated pericardial inflammation^{104, 111} or to pericarditis.⁹⁹ Although a rare entity, left ventricular pseudoaneurysm most commonly occurs as a sequela of myocardial infarction or following cardiac sur-

Figure 32-14. True ventricular aneurysm in a patient with history of myocardial infarction. Axial CT image of the heart after administration of intravenous contrast medium shows marked thinning of the cardiac apex (arrowheads) compared with the thickness of the lateral wall (arrow). There is slight bulging of the apex. Dyskinesia was present on the echocardiogram.

Figure 32-15. Calcified myocardial infarct. Noncontrast-enhanced CT shows dense calcification of the left ventricular apex (arrow) in this patient known to have a history of myocardial infarction. D, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

gery.^{60, 74, 84, 89} Less common causes include trauma, myocardial abscess,⁶⁰ and endocarditis.^{42, 77} Pseudoaneurysms resulting from myocardial infarction occur most commonly in the inferior or posterolateral wall and typically have a narrow neck (Fig. 32-16).^{51, 70, 100} The location of postsurgi-

cal pseudoaneurysms depends on the type of surgery. Unlike the more common true aneurysms of the left ventricle, pseudoaneurysms of the left ventricle are more prone to rupture, resulting in death.^{39, 51, 100, 109, 116}

Coronary artery bypass grafts can be identified on CT

Figure 32-16. Pseudoaneurysm of the left ventricle following myocardial infarction. *A*, Axial image without intravenous (IV) contrast medium shows a curvilinear calcification (arrows) along the inferior aspect of the left ventricle (LV). *B*, Following administration of IV contrast medium, the abnormal area is enhanced (asterisk). *C*, More caudal image shows a mixture of contrast-enhanced blood (C) and thrombus (T) within the pseudoaneurysm. (Courtesy of Stacy Greenspan, D.O., and Chris Peeters, M.D., Colorado Springs, Colo.)

Figure 32-17. Coronary artery bypass grafts. Contrast-enhanced axial CT image shows enhancement of right and left coronary artery bypass grafts (arrows). AA, ascending aorta; DA, descending aorta; LSV, left superior pulmonary vein; RPA, right pulmonary artery; S, superior vena cava.

scans (Fig. 32-17). With faster scanning times, their patency can often be determined. Although it happens rarely, a pseudoaneurysm may develop at the site of the anastomosis, usually the proximal anastomosis. These pseudoaneurysms tend to be identified within weeks to months following bypass surgery and can be associated with mediastinal infection.

True aneurysms are less common and occur in the body of the saphenous graft. They are thought to be related to graft atherosclerosis and are usually identified years after bypass surgery.⁷⁹ They are less likely to rupture than pseudoaneurysms of saphenous vein grafts.¹⁰⁵ Saphenous vein graft aneurysms can be detected on a chest radiograph, where it may have the appearance of a mass.³⁵ CT or magnetic resonance imaging (MRI) demonstrates that the mass is related to a vascular structure, and each modality can depict the amount of associated thrombus within the lumen (Fig. 32-18).

Systemic Disease

The diagnosis of anemia can be suggested on CT scans if an IV contrast agent is not used. In the anemic patient, the blood in the chambers of the heart is less dense than the myocardium because of the reduced protein content in the blood. This difference in density is best appreciated at the level of the interventricular septum (Fig. 32-19). In general, the lower the hemoglobin, the more likely that the myocardium appears denser than the blood. An increase in

density of the myocardium may also be seen in patients with hemochromatosis, because of increased iron deposition within the myocardium. In hemochromatosis, the liver is also increased in density.^{34, 112} Amiodarone is known to concentrate in the heart,⁶¹ and in patients with amiodarone pulmonary toxicity, it has been described as causing increased density of the myocardium on unenhanced CT scans.⁵⁴

Cardiac Tumors

Metastatic involvement of the heart is more common than primary cardiac tumors, which are very rare. Patients with cardiac tumors may be asymptomatic, or they may present with arrhythmias or hemodynamic, embolic, or constitutional symptoms. The reported incidence of cardiac tumors ranges from 0.001% to 0.03%.^{19, 63} Most cardiac tumors have benign histologic features (75%). Although primary cardiac tumors are often evaluated by echocardiography, CT, MRI, or both can be useful in their assessment.

Benign Cardiac Tumors

Myxoma

The most common cardiac tumor, the myxoma, accounts for about 50% of all benign cardiac tumors and 25% of all cardiac tumors. The incidence of cardiac myxoma is 0.5 per million population per year,¹² with a female predominance.^{12, 81} The most common anatomic location is the left atrium (75% to 80%), followed by the right atrium (10% to 20%).^{7, 12, 19, 55, 63} Less common are myxomas involving either ventricle or involving both atria (5% to 10%), and the mitral valve is rarely involved.^{12, 19, 27, 81} Left atrial myxomas are typically pedunculated and arise from the interatrial septum, near the fossa ovalis. Right atrial myxomas tend to be sessile and may arise from areas of the atrium other than the septum.

Patients with myxoma may present with hemodynamic symptoms, embolic disease, or constitutional symptoms.^{12, 55, 81} Hemodynamic symptoms are related to outflow obstruction by the tumor. The symptoms may be related to posture and include dyspnea, syncope, and sudden death. Myxomas are known to embolize, and patients may present with stroke or with symptoms related to peripheral or pulmonary embolization.^{12, 55, 81} Embolization of the myxomatous tissue may result in myxomatous pseudoaneurysm.³² Myxoma may also cause constitutional symptoms, including fever, weight loss, myalgia, and arthralgia.⁵⁵ Patients may also have an elevated erythrocyte sedimentation rate, anemia, and leukocytosis.

Myxomas tend to be solitary and to occur sporadically in middle-aged individuals, although they have been reported in all age groups.^{19, 63, 81} These tumors carry a low risk of recurrence after resections. Familial myxomas tend to occur at an earlier age, can be multiple (a third of cases), and have a 10% risk of recurrence following resection.^{63, 64, 81} Patients tend to present at a younger age than patients with sporadic myxoma. The left atrium is the most common location of familial myxomas (61%).¹⁰⁷

A third subset of myxomas was described by Carney.²⁵

Figure 32-18. Pseudoaneurysm of saphenous vein graft. *A*, Contrast-enhanced axial CT image shows right (curved arrow) and left (arrow) coronary artery saphenous vein bypass grafts. *B*, More caudal image shows enhancement of the right graft (curved arrow). Enhancement of the left graft (arrow) is less certain. *C*, More caudal image shows contrast-enhanced blood within the left graft (arrow). However, the lumen is surrounded by thrombus (arrowheads) within the markedly dilated graft. A, ascending aorta; D, descending aorta; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; P, main pulmonary artery; RA, right atrium; RV, right ventricle; S, superior vena cava.

These myxomas occur in association with pigmented skin lesions and endocrine lesions. Patients tend to present in the third decade of life and tend to have multiple, multicentric, and metachronous myxomas. Only 50% of myxomas involve the left atrium in patients with the Carney complex. Patients with the Carney complex have an increased risk of recurrence of myxoma following resection.⁶⁴ Because the Carney complex is inherited as an autosomal dominant trait, family members should be screened for the disease.^{25, 78}

On CT, a myxoma has the appearance of a filling defect in the chamber of origin (Fig. 32-20). The mass is usually heterogeneous and may have areas of calcification.^{7, 78}

Rhabdomyoma

Rhabdomyomas are the most common pediatric cardiac tumor, typically occurring in children younger than 1 year of age.⁶³ They are usually multiple and occur most commonly in either ventricle, although the atria may also be

involved. They do not occur in association with the heart valves.

Patients are usually asymptomatic. However, the tumors may cause arrhythmias or obstruction, resulting in acute heart failure and sudden death. The incidence of cardiac rhabdomyoma in patients with tuberous sclerosis is 30% to 50%.^{97, 110}

Rhabdomyomas are thought to be hamartomatous lesions. They do not show a significant increase in size and may regress over time^{2, 37, 110}; thus, they may be monitored in asymptomatic individuals. Echocardiography is usually used for evaluation of these tumors.

Other Benign Cardiac Tumors

Cardiac lipomas are usually solitary and may occur in the myocardial tissue or in a subendocardial or subepicardial location. Because affected patients are usually asymptomatic, the lesions are usually found incidentally. Cardiac lipomas can be associated with rhabdomyomas or tuberous

Figure 32-19. Anemia. Axial CT scan without contrast medium in an 18-year-old patient with a hematocrit of 23 mL/dL (normal range, 36 to 47 mL/dL). The interventricular septum (arrowheads) is visible because of the reduced density of the blood in the ventricles. D, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 32-20. Myxoma. This patient presented with symptoms thought to be secondary to mitral stenosis. Axial CT with intravenous contrast medium shows a large mass (M) nearly filling the left atrium. At surgery, the tumor was found to arise from the interatrial septum. LV, left ventricle; RA, right atrium; RV, right ventricle. (Courtesy of Robert D. Tarver, M.D., Indiana University Medical Center.)

sclerosis. These lesions may be first detected by echocardiography. CT or MRI can document their fatty nature, establishing the diagnosis.^{106, 118}

Papillary fibroelastoma is a rare lesion, usually affecting older adults (range, 25 to 86 years of age). The tumor occurs most frequently on the valves, but it can occur anywhere in the heart.^{19, 63} The tumor is composed of multiple papillary fronds, which predispose it to form thrombi. Because of the risk of lethal embolization of the coronary or cerebral circulation, surgical resection is the treatment of choice.^{19, 63} These tumors are usually evaluated with echocardiography. They are not usually seen on CT because of their small size and relation to moving valves.⁷

Cardiac fibromas are the second most common benign pediatric cardiac tumor, although they may also occur in adults. They tend to be solitary lesions that arise in the ventricular myocardium. They may cause lethal arrhythmias and heart failure. On CT, these tumors appear as soft tissue homogeneous masses, often with areas of calcification.⁷ They are often fairly large when detected, and surgical resection may require chamber reconstruction.⁶³

Malignant Cardiac Tumors

Angiosarcoma

Angiosarcoma is the most common primary malignant cardiac tumor.¹⁹ These tumors usually occur in adults, although they have been reported in a wide age range.^{6, 19, 23, 63} Men are affected more often than women.^{19, 47, 63} Angiosarcomas usually arise from the free wall of the right atrium (Fig. 32-21) or from the pericardium.^{8, 19, 23, 47, 63} Thus, patients tend to present with symptoms of right heart failure, vena cava obstruction, or pericardial disease. Most patients have metastatic disease at the time of diagnosis, most commonly involving the lung.²³ The prognosis is generally poor, although some patients survive longer than 1 year.^{6, 19, 23, 47, 63, 98}

Other Malignant Cardiac Tumors

Rhabdomyosarcomas have a slight male predominance and tend to occur in adults. They can arise anywhere within the heart, including the valves, and are frequently multiple. Patients may present with symptoms of pericardial disease, chest pain, dyspnea, or embolic events. Rhabdomyosarcomas are also associated with hypertrophic pulmonary osteoarthropathy, polyarthritis, neurofibromatosis, and eosinophilia.

Fibrosarcomas are rare lesions. They occur in the right and left sides of the heart with equal frequency and are often multiple. Approximately 50% of these tumors involve a cardiac valve.

Primary cardiac osteosarcomas usually arise from the posterior wall of the left atrium near the pulmonary veins.^{6, 19, 21, 63} This is in contradistinction to metastatic osteosarcomas, which usually involve the right atrium. These lesions may calcify and may be confused with calcified myxoma. They can be distinguished from calcified myxomas by their location in the posterior wall of the left atrium instead of the usual septal location of myxomas.

Figure 32-21. Angiosarcoma in a 23-year-old man. Contrast-enhanced axial CT images. A, A large mass occupying most of the right atrium. LA, left atrium; LV, left ventricle; M, mass; RV, right ventricle. B, Image more cephalad shows a filling defect in the right lower lobe pulmonary artery, consistent with tumor thrombus (arrow). The patient had pulmonary and bony metastases as well (not shown). A, ascending aorta; M, mass.

Leiomyosarcomas tend to arise from the posterior wall of the left atrium, typically in the fourth decade of life. They frequently involve the pulmonary veins or the mitral valve, causing symptoms of heart failure.

Liposarcomas are extremely rare lesions, with only 18 reported cases in the literature. Despite their name, histologically little or no fat is detectable. They can occur in the atria, ventricles, or pericardium.

Although up to 25% of patients with *lymphoma* have cardiac involvement at autopsy, primary cardiac lymphoma (lymphoma limited to the heart and/or pericardium) is very rare.¹⁹ Primary cardiac lymphoma is usually a B-cell lymphoma. The most common location is a right-sided lesion, usually arising from the right atrium. Associated pericardial effusion is common (Fig. 32-22).

Secondary Cardiac Tumors

Metastatic cardiac involvement is much more common than primary cardiac neoplasms, but it may be undetected before death. Autopsy studies have found cardiac metastases to be present in up to 20% of patients with neoplasm. They occur most frequently in patients with lymphoma, leukemia, or melanoma (40% to 50%) and in patients with lung or breast cancer (10% to 33%). Direct extension of tumor is the most common route and typically occurs in lung and breast cancers. Symptoms tend to be related to associated pericardial involvement.

Renal cell carcinoma, adrenal carcinoma, hepatocellular carcinoma, and uterine leiomyosarcoma may involve the heart through extension into the inferior vena cava. Thyroid carcinoma may extend through the superior vena cava. Lung cancer may also spread along the pulmonary veins to involve the left atrium.

Finally, lymphangitic metastases may occur as well as hematogenous metastases. Leukemia and lymphoma are the most common tumors to cause cardiac metastases by the lymphangitic route, in which case mediastinal nodes are invariably involved.

Figure 32-22. Primary cardiac lymphoma in a 42-year-old man. Contrast-enhanced CT following open biopsy shows a lobulated mass (M) within the right heart at the level of the tricuspid valve. The mass extends into the right atrial and right ventricular cavities. Open surgical biopsy confirmed the tumor involvement of the tricuspid valve, right atrium, and right ventricle. RA, right atrium; RV, right ventricle.

Figure 32-23. Clot in left atrial appendage in a patient with atrial fibrillation. Axial contrast-enhanced CT images at the level of the left atrial appendage (A and B) and at the level of the left atrium (C) show a low-density filling defect (*asterisk*) in the left atrial appendage extending into the left atrium. This is a typical location for left atrial thrombus. AA, ascending aorta; DA, descending aorta; E, pleural effusion; LA, left atrium; MPA, main pulmonary artery; RPA, right pulmonary artery; S, superior vena cava. The *open arrow* points to the right superior pulmonary vein.

Lesions That Mimic Cardiac Tumors

Thrombus

Thrombus within the heart may mimic a cardiac mass. In the atria, thrombus usually involves the appendages (Figs. 32-23 and 32-24).⁹⁰ Laminated thrombus may also occur in the left atrium between the pulmonary veins.⁹⁰ In the ventricle, thrombus usually occurs over an area of hypokinesis such as a myocardial infarction.^{5, 90} If the diagnosis of clot is uncertain on CT images, MRI can be used for further evaluation.⁹³

Lipomatous Hypertrophy of the Interatrial Septum

Fat may be detected in the atrioventricular grooves and the interatrial septum. Normally, fat in the interatrial septum measures less than 1 cm anterior and posterior to the fossa ovalis.¹⁷ Lipomatous hypertrophy of the interatrial septum (LHIS), first described by Prior in 1964, results in increased fat deposition in the interatrial septum.⁷⁵ This may mimic an atrial tumor on an echocardiogram (Fig. 32-25).^{5, 20} Typically, the lesion is dumbbell-shaped because of the sparing of the region of the fossa ovalis (Fig. 32-26).^{65, 80} Both CT and MRI are able to accurately depict the fatty nature of the lesion and establish the diagnosis.³³

Pathologically, the lesion is not a true encapsulated lipoma. The fatty tissue resembles fetal or brown fat and is intermixed with myocardial cells. This lesion is most often found incidentally, but it can be associated with atrial arrhythmias.^{49, 72, 80} Treatment is directed at controlling the arrhythmia if present.

Figure 32-25. Lipomatous hypertrophy of the interatrial septum. Contrast-enhanced axial image shows fatty enlargement of the interatrial septum (*asterisk*). The fat bulges into the left atrium (LA).

Figure 32-24. Clot in right atrial appendage. Contrast-enhanced axial CT images show (A) a large filling defect in the right atrial appendage (*arrow*) and (B) extension into the right atrium. The right atrium is enlarged. Thrombus was also found in the pulmonary arterial tree (not shown). There is calcification of the left anterior descending artery (*curved arrow*). RA, right atrium. The *arrowheads* point to cusps of aortic valve.

Figure 32-26. Lipomatous hypertrophy of the interatrial septum. Axial CT with intravenous contrast medium shows increased fat deposition within the interatrial septum (*asterisk*). A characteristic bilobed shape is caused by sparing of the fossa ovalis (*arrow*). LA, left atrium; RA, right atrium.

Normal Anatomic Structures

Normal anatomic structures that may be mistaken for a mass include a prominent moderator band in the right ventricle, prominence of the muscle between the left superior pulmonary vein and the left atrial appendage in the left atrium (see Fig. 32-2E), prominent papillary muscles, and a prominent eustachian valve in the right atrium (Fig. 32-27).⁵

Pericardium

The pericardium has two layers: (1) a serous visceral layer (the epicardium), that is adherent to the heart, and (2) a fibrous parietal layer that is attached to the great vessels and the central tendon of the diaphragm. The pericardial space normally contains 20 to 25 mL of pericardial fluid. On CT, the pericardium can be identified when outlined by mediastinal and subepicardial fat. It normally measures only 1 to 2 mm thick.^{18, 31} It is best visualized in the caudal and ventral areas. A focal area of increased thickness can usually be seen just anterior to the right ventricle and near the insertion onto the diaphragm.

Pericardial Defect

Congenital pericardial defects are thought to occur when there is premature atrophy of the left duct of Cuvier, resulting in decreased circulation to the left pleuropericardial membrane. Congenital pericardial defect is reported to occur in 1 in 7000 to 1 in 13,000 in autopsy studies. There is a 3:1 male-to-female ratio.

The defect is usually left-sided and may be partial or complete. Patients are usually asymptomatic; however, herniation of the heart or its appendage into a partial defect may result in chest pain or syncope. Also, sudden death due to herniation of the heart through the defect has been reported.¹⁰⁸ Associated congenital anomalies occur in 20% to 50% of patients with pericardial defect, most commonly atrial septal defect, patent ductus arteriosus, tetralogy of Fallot, bronchogenic cyst, or pulmonary sequestration.^{66, 108} Most patients with pericardial defects have partial left-sided absence.⁶⁶ Much less common are right-sided absence and complete absence of the pericardium.

With a partial left pericardial defect, the typical finding is lack of pericardium covering the main pulmonary artery and the left atrial appendage.⁶⁶ In 75% of patients, there is also a large defect in the adjacent parietal pleura.¹⁰⁸ Chest radiographs of patients with a partial left pericardial defect show a discrete bulge in the cardiomeastinal silhouette at the level of the main pulmonary artery and left atrial appendage. Patients with complete absence of the pericardium show a shift of the heart to the left, a long prominent pulmonary artery, a flattened left heart border, and separation of the cardiac apex and diaphragm by lung. CT may demonstrate absence of the pericardium or an abrupt termination of the pericardium if the defect is partial.⁵⁰ When the left pericardium is absent, lung is interposed between the main pulmonary artery and the ascending aorta. When placed in the left lateral decubitus position, the heart migrates against the left chest wall. Absence of the sternopericardial ligaments may cause the heart to lie in a more posterior position when the patient is supine.¹⁰¹

Acquired pericardial defects also occur and usually follow surgery, although they may be secondary to trauma or to erosion of peptic ulcer disease.¹⁰¹ Coronary artery bypass

Figure 32-27. Prominent eustachian valve. Axial contrast-enhanced CT image shows a finger-like soft tissue projection within the right atrium (*arrow*). A prominent eustachian vein was detected by echocardiography. D, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

graft surgery is the most common cause of a surgical pericardial defect. When a linear midline incision is made, however, it heals readily and herniation does not usually occur.¹⁰¹ Large or small defects in the pericardium may result from creation of a pericardial window, treatment of pericardial constriction, and surgery for lung cancer and mesothelioma. Radiographic detection of a pericardial defect is possible if there is herniation of the heart or demonstration of continuity of gas or fluid within the pleural and pericardial spaces. As with congenital pericardial defects, CT can demonstrate the discontinuity of surgical pericardial defects.¹⁰¹ Acute cardiac herniation through a surgical pericardial defect usually occurs within the first 24 hours of surgery and is often triggered by a change in body position, suctioning, or coughing.¹⁰¹

Pneumopericardium most commonly occurs secondary to trauma, either barotrauma or blunt or penetrating trauma. It may also occur secondary to erosion of the pericardium by tumor, infection, or a stomach or duodenal ulcer.

Pericardial Cyst

Most pericardial cysts are actually pleuropericardial cysts. True pericardial cysts are rare. Pericardial cysts occur in a 3:2 male-to-female ratio. Most patients are asymptomatic. The cysts are most commonly located in the right cardiophrenic angle but can occur at the left cardiophrenic angle or higher in the mediastinum, and they often have a peripherally pointed contour.^{71, 115}

On chest radiographs, the appearance is that of an area of increased soft tissue density at the cardiophrenic angle. CT can demonstrate a sharply demarcated mass whose density is that of water, with very thin or imperceptible walls (Fig. 32-28). Occasionally, the attenuation in a pericardial cyst may be higher than that of water. CT can also document whether there is increased mediastinal fat, which can have a similar appearance on a chest radiograph⁷³ (Fig. 32-29).

Pericardial Effusion

There are many causes of pericardial effusion^{4, 30, 59} (Table 32-1). On CT scans, pericardial effusion is easily detected as an increase in fluid density within the pericardial space. Fluid commonly collects in a location anterior to the right ventricle or lateral to the left ventricle.⁴⁰ Pericardial fluid may collect in one of the pericardial sinuses and may be mistaken for other pathologic processes.

Knowledge of the anatomy of the pericardial sinuses helps one to make the correct diagnosis (Fig. 32-30).^{29, 43, 56, 66} The superior pericardial recess is located anteriorly and extends anterior to the aortic root to the level of the innominate artery.^{29, 43, 56, 66} The superior pericardial recess also extends between the ascending aorta and the main pulmonary artery in a triangular shape. It is continuous with the transverse sinus, which lies posterior to the ascending aorta and the main pulmonary artery.^{29, 43, 56, 66}

Pericardial fluid in the superior pericardial recess may mimic aortic dissection, adenopathy, or an anterior mediastinal mass.^{28, 71, 91, 96} The transverse sinus often has a lenticu-

Figure 32-28. Pericardial cyst. Axial CT scan without contrast medium shows an elongated mass (arrow) arising from the pericardium (arrowheads). The mass, whose density was similar to that of water, was resected and found to be a pericardial cyst.

Figure 32-29. Prominent paracardiac mediastinal fat. This patient was evaluated by CT for a masslike density at the right cardiophrenic angle. Axial CT scan without contrast medium shows a collection of fat (F) at the right cardiophrenic angle, consistent with a prominent fat pad. The thin pericardium is outlined by subepicardial and mediastinal fat (arrowheads).

Figure 32-30. Pericardial effusion. Axial CT images following administration of intravenous contrast medium demonstrate the location of the pericardial recesses.

A, CT image at the level of the ascending aorta and main pulmonary artery. Note fluid collecting in the superior pericardial recess (spr) and the continuity of the superior pericardial recess with the transverse sinus (ts). Although fluid is not detectable in this patient, the superior pericardial recess continues along the anterior aspect of the aorta and the main pulmonary artery superiorly to the level of the aortic arch. AA, ascending aorta; C, calcified lymph node; DA, descending aorta; LPA, left pulmonary artery; P, main pulmonary artery; S, superior vena cava.

B, More caudal CT image shows fluid within the superior pericardial recess (spr), anterior to the ascending aorta (AA) and the main pulmonary artery (MPA). Fluid is also present in the transverse sinus (ts) posterior to the ascending aorta and within the left pulmonary recess (lpr). The left pulmonary recess lies anterior to the left superior pulmonary vein (arrow) and the left mainstem bronchus. C, calcified lymph node; DA, descending aorta; S, superior vena cava.

C, More caudal CT image shows fluid in the superior pericardial recess (spr), the left pulmonary recess (lpr) anterior to the left superior pulmonary vein (curved arrow), and the transverse sinus (ts). There is a tiny amount of fluid posterior to the superior vena cava (S) within the postcaval recess (arrows). AA, ascending aorta; DA, descending aorta; RPA, right pulmonary artery; RV, right ventricular outflow tract.

D, More caudal CT image shows a small amount of fluid within the right pulmonary vein recess (arrow). The right and left pulmonary vein recesses lie between the superior and inferior pulmonary veins on their respective sides. Fluid also lies within the oblique sinus (os) posterior to the left atrium (LA) and anterior to the esophagus (arrowhead). AA, aortic root; DA, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 32-30. Continued.

E, More caudal CT image shows fluid within the inferior aortic recess (iar). This recess is located between the ascending aorta (AA) and the inferior aspect of the superior vena cava (S) or the superior aspect of the right atrium (RA). Fluid is also present in the oblique sinus (curved arrow) and the postcaval recess (arrow), which is posterolateral to the superior vena cava between the right pulmonary artery and the right superior pulmonary vein (rspv).

F, More caudal CT image shows a significant amount of fluid (E) within the inferior aspect of the pericardium. Bilateral pleural effusions are also present (asterisks).

lar shape, which is helpful in distinguishing it from adenopathy.^{9, 10, 13} The oblique pericardial sinus lies behind the left atrium, between the pulmonary veins.^{43, 56} Less commonly identified recesses include the left pulmonic recess located between the left pulmonary artery and the left superior pulmonary vein, the postcaval recess located between the superior vena cava and the right pulmonary artery and right superior pulmonary vein, and the pulmonary venous recess located between the superior and inferior pulmonary veins.^{43, 56, 76}

Thickening of the pericardium, which may show enhancement following administration of IV contrast medium, may be seen in patients with pericarditis.⁷¹ CT can document hemopericardium by showing the increased attenuation of blood within the pericardial space (Fig. 32-31).⁷¹

Table 32-1. Etiology of Pericardial Effusion

1. Infection (viral, bacterial, fungal, parasitic)
2. Inflammatory (sarcoid, amyloid, inflammatory bowel disease, Whipple's disease, temporal arteritis, Behçet's syndrome)
3. Immunologic (postinfectious, postcardiac injury, postcardiotomy, postinfarction, rheumatic fever, systemic lupus erythematosus, rheumatoid arthritis, Still's disease, ankylosing spondylitis, Reiter's syndrome, scleroderma, mixed connective tissue disease, Wegener's granulomatosis, Churg-Strauss syndrome)
4. Traumatic (hemopericardium, pneumopericardium, radiation)
5. Uremic
6. Neoplastic
7. Hypothyroidism
8. Chylopericarditis
9. Congestive heart failure

Figure 32-31. Hemopericardium in patient after coronary artery bypass graft surgery. Axial CT scan without contrast medium shows filling of the pericardial space (asterisks), which measured 59 HU, consistent with blood. The pericardial space is separated from the heart by a thin layer of subepicardial fat (arrowheads).

Figure 32-32. Postradiation pericardial thickening. Axial contrast-enhanced CT image shows marked thickening of the visceral and parietal pericardium (*arrows*). The patient had received radiation for lung carcinoma.

Figure 32-33. Constrictive pericarditis. *A*, Axial contrast-enhanced CT image at the level of the ventricles shows bilateral dense calcification of the pericardium at the level of the atrioventricular grooves (*arrows*). *B*, Scan at the level of the left atrium shows an additional area of calcification anteriorly (*arrow*). The superior vena cava is larger than the descending aorta. *C*, Scan at the level of the diaphragm shows inferior pericardial calcification (*arrow*). The inferior vena cava is more than twice the size of the descending aorta. A, aortic root; D, descending aorta; I, inferior vena cava; LA, left atrium; RV, right ventricular outflow track; S, superior vena cava.

Constrictive Pericarditis

Constrictive pericarditis is a possible sequela in patients with previous pericardial disease, including idiopathic pericarditis, infectious pericarditis, connective tissue disease, neoplastic involvement of the pericardium, postsurgical inflammation, post-radiation therapy pericarditis (Fig. 32-32), uremic pericarditis, and drug-related pericarditis.³⁸ However, some patients have no known antecedent event. Patients usually present with dyspnea, peripheral edema, and ascites.

Echocardiography demonstrates elevated diastolic filling pressures because the constricting pericardium prevents normal diastolic filling of the heart. Because it is often difficult for echocardiography to distinguish between constrictive pericarditis and restrictive cardiomyopathy, patients may be further evaluated with CT or MRI to determine whether the pericardium is thickened.³⁸ CT has the advantage of better depicting calcium within the pericardium.

The CT signs of constrictive pericarditis include (1) diffuse, focal, or annular pericardial thickening or calcification; (2) enlargement of the atria or atrium; (3) dilatation of the superior or inferior vena cava; (4) tubelike configuration of the ventricles and narrowing of the atrioventricular groove; and (5) alteration of the normally straight inter-ventricular septum (Fig. 32-33).³² The constriction can be global or unilateral, or it may affect the atrioventricular groove.

Pericardial Tumors

Metastatic disease, the most common cause of neoplastic involvement of the pericardium, has been reported in up

to 20% of autopsy studies. Most patients with pericardial metastases have metastatic disease elsewhere in the body.^{53, 115} The most common primary tumors that involve the pericardium secondarily include lung (33%) and breast cancer (25%) and lymphoma/leukemia (15%).^{46, 53, 115} Metastatic routes include hematogenous and lymphangitic spread as well as direct extension.

In many cases, the metastases are not radiographically detectable. Pericardial effusion in a patient with a known malignancy should arouse suspicion of metastatic involvement of the pericardium, although nonmalignant causes of pericardial effusion, such as radiation or drug-induced pericarditis, must also be considered. Occasionally, soft tissue nodules or masses may be demonstrated on CT (Fig. 32-34).

CT is often better than echocardiography in detecting pericardial masses. Subepicardial fat may mimic a pericardial mass on echocardiography, and in some cases a mass within the pericardium cannot be distinguished from pericardial effusion.^{41, 67}

Primary tumors of the pericardium include mesothelioma, sarcoma, lymphoma, teratoma, and pheochromocytoma.^{45, 53} Intrathoracic paragangliomas account for only 1% to 2% of all pheochromocytomas. The most common intrathoracic location of paragangliomas is the posterior mediastinum. Intrapericardial location is very rare.⁴⁵ Tumors tend to be large and are most commonly located adjacent to or involving the left atrium.^{6, 45} Typically, pericardial mesothelioma presents with diffuse involvement of the pericardium (Fig. 32-35). Any cardiac involvement is usually superficial, and this finding is helpful in distinguishing mesothelioma from pericardial angiosarcoma, which typically has more extensive involvement of the heart.^{19, 63}

Figure 32-34. Pericardial metastases from renal cell carcinoma. A, Axial contrast-enhanced CT at a level just inferior to the heart shows a large pericardial effusion (E). Two soft tissue nodules are identified arising from the parietal pericardium (arrowheads). B, Scan performed 6 months later shows filling of the pericardial space with enhancing soft tissue (arrows).

Figure 32–35. Pericardial mesothelioma. Axial contrast-enhanced CT scan shows a large mass (M) arising from the right pericardium, invading the right atrium, and encasing the inferior vena cava (arrow). The patient was initially seen at an outside hospital, where the mass was thought to be arising from the lung. Bronchoscopic findings were negative. The patient was referred for biopsy. E, effusion.

Magnetic Resonance Imaging of the Heart

Anna Rozenshtein, Lawrence M. Boxt

Magnetic resonance imaging (MRI) provides diagnostic morphologic and functional information for the evaluation and management of patients with congenital and acquired cardiovascular disease. The usefulness of cardiac MRI lies in adaptation of motion-suppression techniques to cancel out complex cardiac contractile motion. Thus, the most important difference between cardiac and other-organ MRI is the application of electrocardiographic (ECG) gating to the acquisition pulse sequence to suppress contraction-motion artifacts. ECG gating acts by applying a timing signal coincident with cardiac motion to image acquisition.^{160, 161, 168, 322} That is, by timing each phase-encoding step in an MRI acquisition to a particular point in the ECG cycle of the heart, reconstructed images are temporally coherent. By convention, the R-wave is chosen as the gating signal because it has the greatest voltage and is therefore easily identified from the ECG (Fig. 33-1). In addition, because the peak of the R-wave indicates the commencement of electromechanical ventricular contraction, images immediately following the R-wave are obtained at ventricular end-diastole, a time when the ventricles are most dilated.

For an image containing N-phase encoding steps, N cardiac cycles, or heartbeats, are needed to acquire an image at one particular phase of the cardiac cycle. Improved acquisition software provides more efficient use of the cardiac cycle. That is, by pulsing several anatomic levels, each at different delays after the R-wave, we can perform multisection spin-echo acquisition.

Short, flip-angle, gradient-echo cine (*cine*) imaging^{226, 272} allows acquisition of images of the heart with greater temporal resolution, permitting evaluation of ventricular function, valvular regurgitation or stenosis, and abnormal hemodynamics in congenital heart lesions. When this pulse

sequence is used, the same anatomic section is excited with radiofrequency (RF) pulses using a short repetition time (TR) of 5 to 15 msec. The temporal resolution of the examination depends on the repetition time and heart rate. That is, a faster heart rate results in a shorter ECG RR interval (the time between R-waves) and, for any given number of discrete phases of the cardiac cycle, less time between phases. After a fixed number of excitations, the imaging system waits for the next R-wave to advance to the next phase-encoding step.

In some circumstances, an adequate ECG tracing may not be obtained before the examination is begun. This may occur in patients with low cardiac voltage, such as in pericardial effusion. In these individuals, an adequate gating signal may be obtained by application of a peripheral pulse sensor. Peripheral pulse gating (PPG) produces images of diagnostic quality, but one must take care to visually inspect imagery prior to functional analysis. That is, the peak of the peripheral pulse, the timing signal for image acquisition, is delayed in time from the ECG R-wave. Therefore, series of gradient-reversal images do not begin with the end-diastolic image and run through the cardiac cycle toward end-systole. Rather, the first image in each acquisition is obtained at a variable delay after end-diastole. Thus, the series of images acquired at each anatomic level begins somewhere in the cardiac cycle and passes through end-diastole and end-systole, out of phase with a conventionally acquired ECG-gated acquisition. The delay between the ECG R-wave and the peak of the peripheral pulse is a function of the distance between the heart and the monitored extremity artery as well as the biomechanical properties of the aorta and its branches. Series of images obtained using PPG may be of diagnostic quality for morphologic analysis, but cine examinations obtained with PPG should be analyzed with caution.

Recent advances in image-acquisition software have greatly reduced imaging time and allowed acquisition of images during a single breath-hold, thus eliminating motion artifacts and the need for respiratory gating. This is true for the gradient-echo cine acquisitions, as well as the relatively new sequences ideally adapted for morphologic imaging, such as double-inversion recovery techniques.

The high-contrast resolution of spin-echo acquisition (see appendices at the end of this chapter) allows confident differentiation between intraventricular blood and myocardium, necessary for detailed analysis of the epicardial and endocardial borders.¹³⁷ Acquisition of gradient-echo cine imagery in the axial plane displays the character of ventricular contraction, including the orientation of the interven-

Figure 33-1. Diagram of three beats from a stereotypic electrocardiographic (ECG) strip. The P-, R-, and T-waves are labeled. The RR interval is defined as the time between cardiac cycles and is chosen for the repetition time (TR) in ECG-gated acquisitions. The standard is an arbitrary voltage used for comparison with the ECG voltage. Any signal whose voltage is greater than the standard is chosen as the R-wave for gating purposes.

tricular septum, and the status of the cardiac valves. The high temporal resolution of cine gradient-echo acquisition allows acquisition of ventricular imagery at both end-diastole and end-systole. From these acquisitions, ventricular cavity volume^{29, 86, 180, 205, 271, 292} and myocardial mass^{141, 142} may be calculated.

Because MRI requires no assumptions about the shape

of the ventricular chamber, end-diastolic and end-systolic ventricular chamber volume is obtained directly by calculating the sum of planimetered ventricular cavity areas times slice thickness through the entire chamber. Left and right ventricular end-diastolic and end-systolic volumes may be calculated, and from these data, stroke volume (the difference between end-diastolic and end-systolic volume),

Figure 33-2. Construction of the cardiac short axis and analysis of cavity volume and myocardial mass.

A, Sagittal scout image obtained through the posterior right sinus of Valsalva. From this image, an acquisition is obtained in the coronal plane AB.

B, Coronal scout image through the posterior right sinus of Valsalva (r). The two papillary muscles (arrows) are well demonstrated. The innominate vein (IV), main pulmonary artery (PA), ascending aorta (Ao), and right atrium (RA) are labeled. From this image, an oblique axial image is prescribed in plane CD through the aortic valve and left ventricular (LV) apex.

C, The anteroposterior rotation of the heart is compensated for by prescribing a plane (EF) through the mitral valve (arrow) and the left ventricular (LV) apex. The right ventricle (RV) and the aortic root (Ao) are labeled.

D, In this section, the line (GH) drawn between the middle of the mitral valve and the apex of the left ventricle (LV) defines the long axis of the LV, its axis of rotation. Images obtained at right angles to this line are in the cardiac short axis. The left atrium (LA), the left upper lobe pulmonary artery (long arrow), and the ostium of the left atrial appendage (laa) are labeled.

ejection fraction (stroke volume divided by end-diastolic volume), and cardiac output (stroke volume \times heart rate) may be computed (Fig. 33-2).

In a similar manner, ventricular mass is obtained by summing the volume of myocardium in each image slice over the entire heart. For each tomographic slice, the myocardial volume is the difference between the areas of the epicardial and the endocardial borders times the slice thickness. The sum of the volumes of myocardium times the specific gravity of myocardium (1.05 g/mL) is the myocardial mass.

In principle, these computations can be performed using images obtained in any anatomic section. In practice, however, images obtained in the cardiac short axis are usually

used for this purpose. Thus, MRI not only reliably demonstrates morphologic ventricular abnormalities but also allows quantitation of ventricular function (Table 33-1) under pathologic conditions.

In this chapter, we review the use of ECG-gated spin-echo and cine gradient-echo MRI techniques for the diagnosis and evaluation of patients with congenital and acquired heart disease. The clinical role of MRI in the management of these patients differs from medical institution to institution. Availability of MRI scanners configured for cardiac imaging, availability of trained personnel to scan and interpret examinations, and patient referral patterns all affect the volume of clinical cardiac MRI performed at any institution. Nevertheless, the volume of

Figure 33-2 Continued.

E, End-diastolic short-axis section through the papillary muscles (p) of the left ventricle (LV). The right ventricle (RV) is labeled. The interventricular septum bows toward the RV and is shared by both the left ventricle and the right ventricle.

F, Same anatomic location, as in *E*, image obtained at end-systole. Note the symmetrical thickening of left ventricular and right ventricular myocardium and the diminution of the LV and RV cavity area.

G, The endocardial left ventricular border has been traced. The papillary muscle that appears to be attached to the LV wall (p1) is excluded from the LV cavity; the muscle separated from the wall (p2) is included.

H, Similarly, the endocardial borders of both the left and right ventricles are traced.

I, The epicardial borders of the left and right ventricles are traced.

TABLE 33-1. Left and Right Ventricular Cavity (Volume, Mass, and Derived Values Indexed for Body Surface Area)

Index	Value
Right Ventricle	
End diastolic volume index (RVEDVI)	$67.9 \pm 13.4 \text{ mL/M}^2$
End systolic volume index (RVESVI)	$27.9 \pm 7.5 \text{ mL/M}^2$
Stroke volume index (RVSVI)	$40.1 \pm 9.7 \text{ mL/M}^2$
Ejection fraction (RVEF)	0.59 ± 0.09
Mass index	$23.3 \pm 1.4 \text{ g/M}^2$
Left Ventricle	
End diastolic volume index (LVEDVI)	$68.9 \pm 13.1 \text{ mL/M}^2$
End systolic volume index (LVESVI)	$27.1 \pm 7.8 \text{ mL/M}^2$
Stroke volume index (LVSVI)	$41.8 \pm 10.9 \text{ mL/M}^2$
Ejection fraction (LVEF)	$0.60 \pm 0.11 \text{ g/M}^2$
Mass index	$91.6 \pm 3.2 \text{ g/M}^2$

Data from Box LM, Katz J, Kolb T, et al: J Am Coll Cardiol 19: 1508–1515, 1992; and Katz J, Whang J, Box LM, Barst RJ: J Am Coll Cardiol 21: 1475–1481, 1993.

cardiac MRI cases performed is increasing, and examinations are performed and interpreted at more and more institutions.

This chapter is best used as a handbook for planning, performing, and interpreting a cardiac MRI study. As the reader will find, although much has indeed been said, much has also been left out. We have made few comments about pulse-sequence parameters. These are set at each site during installation and applications training on the scanner. On the other hand, we pay much attention to pathophysiologic mechanisms and their effect on cardiac morphology and function as displayed in MR images. Our decided emphasis on the medical aspects of the cardiac diseases studied by MRI is intended not only to point out the usefulness of MRI in evaluating the heart but also to help radiologists in planning, performing, and interpreting cardiac MR images with a basic **collection of medical data** to engage in this practice.

Pericardial Diseases

The pericardium consists of the visceral pericardium (epicardium), the parietal pericardium, and the 20- to 60-mL cavity contained between them. The epicardium is a monolayer of mesothelial cells that covers the external surface of the heart. Beneath the epicardium is either myocardium or epicardial fat. This layer extends for short distances along the pulmonary veins, the superior vena cava below the azygos vein, the inferior vena cava, the ascending aorta to a point 20 to 30 mm above the root, and the main pulmonary artery as far as its bifurcation. It then reflects on itself to become the parietal pericardium, which is a 1-mm-thick outer fibrous layer composed of dense collagen lined on the inside by a monolayer of mesothelial cells.

The visceral pericardium is normally thin and is therefore not visualized separately by any imaging modality. The combination of the visceral pericardium and the small volume of physiologic pericardial fluid constitutes the normal pericardium routinely visualized on MR images as a 1- to 2-mm-thick layer^{274, 290} (Fig. 33-3) that can appear focally thicker at the sites of its major attachments. On

Figure 33-3. Short-axis section from a patient without cardiac disease. The right ventricle (RV), main pulmonary artery (PA), and left ventricular cavity (LV) are labeled. The signal voids of the anterior descending (long black arrow) and circumflex (long white arrow) coronary arteries are identified. The pencil-thin signal void of the anterior aspect of the pericardial space (short black arrows) extends to the top of the pulmonary artery.

spin-echo MRI scans, the normal pericardium appears as a pencil-thin line of low signal intensity between the epicardial and pericardial fat. The low signal intensity is attributed to the fibrous nature of the parietal pericardium, the low protein content of pericardial fluid,³¹⁷ and the nonlaminar flow patterns caused by cardiac pulsation.³⁰⁹

The reflection of pericardium around the great arteries and veins forms the two pericardial “appendages.” Anterior to the aorta this contiguous pericardial space is called the *preaortic recess*; posteriorly, it is called the *retroaortic* or *superior pericardial recess* (Fig. 33-4). Posterior and lateral to the heart, the extraparenchymal pulmonary veins and the superior and inferior venae cavae are enveloped by the venous mesocardium, which has the shape of an inverted U. The intrapericardial space between the pulmonary veins is called the *oblique sinus*. It is essential to appreciate the anatomic extent and location of these pericardial sinuses because they are normally seen on MRI^{134, 194} and may be confused with adenopathy^{5, 165} or aortic dissection.^{55, 165}

Congenital Absence of the Pericardium

Congenital absence of the pericardium is a malformation that is thought to be due to compromise of the vascular supply to the pleuropericardial membrane that surrounds the ventral cardiac tube during embryologic development. Pericardial defects may vary in size from small communications between the pleural and pericardial cavities to complete (bilateral) absence of the pericardium. The most common form is complete absence of the left pericardium, with preservation of the pericardium on the right.

Noninvasive modalities, such as contrast-enhanced CT

Figure 33-4. Axial spin-echo image. The ascending aorta (Ao), descending aorta (AoD), main pulmonary artery (MPA), left pulmonary artery (LPA), superior vena cava (SVC), left bronchi (LB), right bronchi (RB), and azygos vein (az) are labeled. The superior pericardial recess is seen as a signal void (arrows) behind the ascending aorta and anterior to the right pulmonary artery (RPA).

and MRI, have replaced diagnostic pneumothorax and cardiac angiography as the methods of choice^{18, 118, 266} for definitive diagnosis of this abnormality. In particular, the multiplanar capabilities of MRI allow direct identification of the absent segment of the parietal pericardium, demonstration of contact between the heart and lung,¹¹⁸ or recognition of profound leftward displacement and rotation of the heart in the chest (Fig. 33-5).

Pericardial Cysts and Diverticula

If a portion of the pericardium pinches off from pleuro-pericardial membrane during embryologic development, a cyst forms, containing the same mesothelial lining as the normal pericardium. Similarly, a pericardial diverticulum is a failed cyst; communication with the pleural space persists (Fig. 33-6). Both lesions appear on spin-echo MRI acquisition as fluid-filled²⁷³ paracardiac masses whose signal intensity increases in subsequent multiecho spin-echo images.²⁷³ Gradient-echo acquisition reveals isointensity with rapidly moving blood.

Acquired Pericardial Disease

Normal pericardium most commonly responds to insult by cellular proliferation or the production of fluid or fibrin;

Figure 33-5. Congenital absence of the pericardium. *A*, Coronal spin-echo acquisition. The aortic arch (Ao) displaces the trachea (T) to the right. The aortic arch, the main pulmonary artery (MPA), and, in fact, the entire heart, are displaced into the left chest. Despite the apparent size of the MPA, the right ventricular (RV) cavity appears normal and the RV free wall myocardium (arrows) is of normal thickness. LV, left ventricle; RPA, right pulmonary artery. *B*, Axial spin-echo acquisition through the main pulmonary artery (MPA) and right pulmonary artery (RPA). The ascending aorta (Ao) and the main pulmonary artery are displaced toward the left. The MPA is smaller in caliber than the ascending aorta, indicating no increase in pulmonary blood flow. AoD, descending aorta; SV, superior vena cava. *C*, Axial spin-echo image through the cavities of the right ventricle (RV) and left ventricle (LV). Not only is the heart displaced into the left chest; it is rotated in a clockwise manner. AoD, descending aorta; IVC, inferior vena cava; RA, right atrium.

Figure 33-6. Pericardial diverticulum. Spin-echo acquisitions of a widened mediastinum in a 48-year-old man. **A**, In an axial section, an intermediate-signal-intensity mass, itself surrounded by fat, surrounds the left subclavian artery (L). TR = 485 msec, TE = 20 msec. **B** and **C**, Right anterior oblique sagittal section. TR = 485. Multi-echo acquisition; TE in **B**, 20 msec, TE in **C** = 30 msec. **B**, In this first-echo image, the intermediate-signal-intensity mass is again demonstrated. **C**, In this second-echo image, the signal intensity of all structures has decreased, whereas the signal intensity of the mass has apparently increased, indicating a fluid-filled cyst. At operation, continuity with the pericardial space was demonstrated, defining the mass as a diverticulum.

these responses can happen independently or in combination.²⁵¹ The most common manifestation of acute pericarditis is an effusion. The fluid may be serous with a clear transudate, or exudate, varying in nature with the underlying cause. Transudative pericardial effusion may develop after cardiac surgery³¹⁹ or in congestive heart failure, uremia, postpericardiectomy syndrome,¹⁴⁰ myxedema, and collagen vascular diseases. Hemopericardium may be found in trauma, aortic dissection, aortic rupture,¹⁹⁶ or neoplasm (especially primary pericardial mesothelioma).³ Chylopericardium resulting from injury or obstruction of the thoracic duct is rare.

MRI is helpful for characterizing pericardial effusions. On spin-echo examination hemorrhagic effusion presents as areas of mixed low, intermediate, and high signal intensity, depending on the age of blood products (Fig. 33-7). Non-hemorrhagic effusions on spin-echo MRI have predominantly low signal intensity (Fig. 33-8),²⁷³ as a result of spin

phase change³⁰⁹ of the pericardial fluid. Gradient-echo MRI sequences display freely mobile pericardial fluid that has high signal intensity. Inflammatory effusion, as seen in uremia, tuberculosis, or trauma, may have medium-signal-intensity components^{142, 273} on spin-echo MRI, especially in dependent areas.¹⁴² It has been suggested²⁷³ that the latter may be due to high-protein content of inflammatory pericardial fluid.²⁵¹ Furthermore, because adhesions are common in pericardial inflammation, inflammatory effusions may not have the normal free-flow patterns of pericardial fluid that may lead to loci of increased signal intensity on spin-echo MRI, similar in appearance to loculated pericardial effusions (Fig. 33-9). Despite these complex signal characteristics, MRI helps in distinguishing inflammatory pericardial thickening and adhesions from fluid accumulation (intermediate versus predominantly low signal intensity).^{142, 273} Fibrous pericardial thickening appears as a low-signal-intensity band surrounding the heart. Pericardial inflammation, as seen in

Figure 33-7. MR images obtained from a 53-year-old man who received a heart transplant 36 hours earlier, now with a widened mediastinum and cardiac silhouette. *A*, Coronal spin-echo acquisition shows a rim of increased signal intensity (arrows) surrounding the lateral border of the right atrium, above the top (**) of the main pulmonary artery (PA), and in the space between the ascending aorta (Ao) and pulmonary artery (***). LV, left ventricle; RV, right ventricle. *B*, Axial section through the right ventricular outflow tract (RVO). Increased signal intensity surrounds the right atrial appendage (RAA) and is insinuated between the ascending aorta (Ao) and RVO. LA, left atrium.

Figure 33-8. MR image obtained from two patients with simple pericardial effusions. *A*, The patient is a 64-year-old man with progressive shortness of breath. In this oblique axial section through the posterior right aortic sinus of Valsalva (pr), the parietal pericardium (arrows) is separated from the epicardial surfaces of the heart. The left ventricle (LV), right ventricle (RV), left atrium (LA), and right atrium (RA) are labeled. Note the bilateral pericardial effusions (eff) as well. *B*, In this axial gradient-echo acquisition (in another patient), the high-signal-intensity serous pericardial fluid surrounds the heart. AoD, descending aorta; LV, left ventricle; RV, right ventricle.

Figure 33-9. Complex pericardial thickening and loculated effusion in pericarditis. Coronal spin-echo acquisition demonstrates increased signal intensity within the pericardial space (* * * *) external to the epicardial fat along the inferior aspect (arrow) of the right atrium (RA) and left ventricle (LV). In addition, note how thick the pericardium is as it reflects on the main pulmonary artery segment (PA) and ascending aorta (Ao). The left atrial appendage (arrow 1) is contained within the pericardium. The proximal left anterior descending coronary artery (arrow 2) is identified.

uremic or tuberculous pericarditis or trauma following resuscitation, appears as increased signal intensity compared with myocardium on spin-echo MRI acquisition (Fig. 33-10).²⁷³

Pericardial Tamponade

Gradual accumulation of pericardial fluid may not produce clinical signs or symptoms. However, rapid accumulation of as little as 100 to 200 mL of fluid can impede diastolic ventricular filling. Pericardial tamponade is a condition in which reduced stroke volume limits maintenance of cardiac output. MRI is often instrumental in suggesting the cause of the effusion (i.e., hemorrhage, neoplastic involvement, inflammation due to tuberculosis or other infectious processes) in this acutely emergent situation.

Pericardial Constriction

The hallmarks of pericardial constriction are pericardial thickening and calcification and abnormal diastolic ventric-

ular function. In most cases, constrictive pericarditis involves the entire pericardium, compromising filling of all cardiac chambers. Occasionally, however, local chronic pericardial thickening has been reported.^{54, 214} Focal pericardial thickening is more commonly seen in the postoperative patient and is frequently located anterior to the right ventricle.¹⁸⁴ The clinical findings of constrictive pericarditis overlap with those of restrictive cardiomyopathy, a primary disorder of the myocardium. Differentiation between these two entities is imperative because patients with pericardial constriction may benefit from pericardiectomy²³¹; myocardial restriction may be rapidly progressive and necessitate cardiac transplantation.

Symptomatic pericardial constriction can be seen in the absence of conventional radiographically detectable pericardial thickening, however. Masui and associates¹⁸⁴ found pericardial thickening on MR images in 88% of cases of proven constrictive pericarditis. Pericardial thickening is not diagnostic of pericardial constriction²⁷³; demonstration of pericardial thickening greater than 4 mm (Figs. 33-11 and 33-12) in the face of characteristic hemodynamic findings distinguishes constrictive pericarditis from restrictive cardiomyopathy.^{184, 273} Normal pericardium on MR²⁹⁰ is less than 4 mm in thickness.

ECG-gated spin-echo MRI is an ideal method of investigating the pericardium.^{134, 142, 194, 273, 290} It is exquisitely sensitive to changes in pericardial thickness as well as to morphologic and functional changes in the atria and ventricles resulting from focal or diffuse pericardial disease. In pericardial constriction, the right ventricle may appear tubular (see Fig. 33-12).²⁸⁷ Gradient-echo acquisition demonstrates decreased right ventricular contractile function and limited diastolic excursion, common to both restriction and constriction. Dilatation of the right atrium, venae cavae, coronary sinus, and hepatic veins, reflecting right heart failure, may be seen in patients with constrictive pericarditis as well as in patients with restrictive cardiomyopathy.

Figure 33-10. MR image obtained from a 68-year-old man, 8 years after coronary artery bypass surgery, who is now complaining of shortness of breath. There is a left pleural effusion (eff). Thickened pericardium (arrows) surrounds the lateral aspects of the right atrium (RA) and the anterior aspect of the tubular right ventricle (RV). The coronary sinus (CS) is mildly dilated. IVC, inferior vena cava.

Calcium does not produce an MRI signal. Therefore, on spin-echo MRI, calcification appears as loci of irregular signal voids separating the epicardial and pericardial fat. In constrictive pericarditis, the circumcardiac signal void of the pericardial space is irregular and can be identified in more images and different sections.²⁸⁷

Spin-echo and gradient-echo MRI also can accurately evaluate the thickness of the posterior left ventricular wall in patients with constrictive pericarditis. The latter has prognostic significance, because the most common cause of myocardial dysfunction after pericardiectomy is myocardial atrophy.⁷⁶ Radiographic demonstration of thinning of the free wall of the left ventricle due to myocardial atrophy was associated with markedly increased mortality after pericardiectomy.^{240, 241}

Pericardial Neoplasms

The wide field of view, excellent contrast resolution, and multiplanar capability of MRI make it a method of choice for the diagnosis and evaluation of pericardial neoplasms.^{2, 19, 173, 247} Primary pericardial neoplasms are rare. Malignant mesothelioma is the most common primary pericardial malignancy. Primary pericardial lymphoma has also been reported.²⁶⁷ Teratomas of the pericardium may also be malignant and are most commonly seen in children.

Whether from lymphangitic or hematogenous spread or by direct invasion, pericardial metastases are uncommon^{58, 318} and, when found, are usually associated with widespread malignant disease.⁶⁹ Metastatic breast carcinoma is the most common pericardial malignancy in women; metastatic lung carcinoma is the most common in men. These lesions are followed in incidence by lymphoproliferative malignancies and melanoma.⁶⁹

Figure 33-11. Pericardial constriction. Axial spin-echo image obtained at the dome of the right hemidiaphragm in a 59-year-old man with previous coronary artery bypass surgery reveals irregular thickening of the pericardium (*arrows*) extending from the atrioventricular ring to the posterior left ventricular wall. Note the right pericardial effusion (*eff*) and dilated inferior vena cava (IVC).

Figure 33-12. MR images obtained from a 23-year-old college student with shortness of breath. The upper gradient-echo acquisition obtained at ventricular end-diastole (ED) shows pericardial thickening increasing the distance between the cavity of the right atrium and the lateral aspect of the heart (*arrows*). The lower figure obtained at end-systole (ES) shows little change in the volume of the ventricles and a characteristic tubular appearance of the right ventricle (RV). Bilateral pleural effusion is evident. LV, left ventricle.

Pericardial effusion is the most common finding in patients with pericardial malignancy. Uncomplicated free-flowing pericardial fluid demonstrates low signal intensity on T1-weighted spin-echo MRI sequences (see Figs. 33-7 to 33-9).^{273, 297} Hemorrhagic effusion, frequently associated with primary malignant mesotheliomas,³ may present as areas of high, low, or medium signal intensity, depending on the age of hemorrhage.²⁷³

Focal or generalized pericardial thickening may also be found in patients with malignant pericardial involvement. Direct invasion can be inferred if the normally pencil-thin pericardium appears thickened or interrupted in close proximity to a neoplasm (Fig. 33-13). MRI is useful in suggesting the origin of the neoplasm. Intrapericardial neoplasms compress and deform the normal intrapericardial structures, whereas extrapericardial masses tend to displace the intrapericardial structures without compression or distortion.^{106, 162}

Malignant pericardial neoplasms tend to be bulky, often

Figure 33-13. MR image of a left pleural mesothelioma in a 66-year-old man. Oblique sagittal spin-echo acquisition shows the markedly thickened pleural mass (M), with thickening of the pericardium (arrows) surrounding the posterior left ventricle (LV). There is a break in the pericardium (arrowhead) where the mass has penetrated to the left ventricular myocardium. RV, right ventricle.

The mass is inhomogeneous in signal intensity, and confined to or immediately contiguous with the pericardium and pericardial space (Fig. 33-14). MRI is excellent at providing information regarding the size, location, and extent of pericardial involvement but is not tissue specific. The fatty tumors (lipomas, fat-containing teratomas) are the exception because of their increased signal intensity on spin-echo T1-weighted MR images. Fatty tumors must be differentiated from focal deposits of subepicardial fat and non-neoplastic lesions (such as mesenteric fat in a hiatal hernia) and focal hemorrhage.

septated, inhomogeneous in signal intensity, and confined to or immediately contiguous with the pericardium and pericardial space (Fig. 33-14). MRI is excellent at providing information regarding the size, location, and extent of pericardial involvement but is not tissue specific. The fatty tumors (lipomas, fat-containing teratomas) are the exception because of their increased signal intensity on spin-echo T1-weighted MR images. Fatty tumors must be differentiated from focal deposits of subepicardial fat and non-neoplastic lesions (such as mesenteric fat in a hiatal hernia) and focal hemorrhage.

Left-Sided Heart Disease

Pathophysiology of Myocardial Infarction

Myocardial infarction is usually caused by thrombotic occlusion of an epicardial coronary artery.³² Lack of oxygen supply to the myocardium downstream from the occlusion leads to anaerobic glycolysis with resultant accumulation of lactic acid and other by-products. Within an hour of the initial ischemic insult, subendocardial infarction ensues, subsequently progressing outward toward the subepicar-

dium. The transmural pattern of progression is related to the greater systolic wall stress and oxygen consumption in the subendocardial zone, as well as limited subendocardial collateral flow, which is preferentially shunted to the subepicardial region. This pattern of transmural progression of myocardial infarction is otherwise known as the wavefront of myocardial necrosis.^{238, 239}

The infarction is usually completed by 6 hours after occlusion. If reperfusion occurs within this period, potentially viable cells may recover. The reduction of the infarct

Figure 33-14. MR images of recurrent pericardial sarcoma in a 58-year-old man. A, Coronal spin-echo acquisition shows this 15 × 20 cm inhomogeneous mass elevating and displacing the main pulmonary artery (PA), the right pulmonary artery (RA), and the ascending aorta (Ao). LA, left atrium. B, Axial section through the displaced right pulmonary artery (RPA) again shows the mass sitting on the roof of the left bronchus (LB). Ao, ascending aorta; AoD, descending aorta; MPA, main pulmonary artery; RB, right bronchus; SVC, superior vena cava.

size achieved by timely reperfusion is predominantly due to the salvage of ischemic but viable subepicardial myocardium. Viable cells also exist in the "border zone" on the lateral margins of the infarct. However, the border zone is narrow and not quantitatively significant.^{83, 339}

MRI Examination of Ischemic Heart Disease

Analysis of changes in regional signal intensity after bolus injection and first-pass transit of MRI contrast medium is gaining acceptance for evaluation of myocardial perfusion. Alternative techniques include the use of endogenous tracers, such as deoxyhemoglobin (blood oxygenation level-dependent pulse sequences), spin tagging of arterial water,^{6, 330} and the use of intravascular rather than extracellular contrast agents.^{41, 154, 242} Intravascular contrast agents, such as ultra-small superparamagnetic iron oxide (USPIO) particles and gadolinium (Gd) chelates (Gd bound to large molecules, such as albumin) remain for a considerable time in the vascular space and thus do not require first-pass imaging.⁸⁰

Assessment of first-pass myocardial perfusion can be obtained by means of fast gradient-echo and echo-planar imaging techniques. Perfusion studies for detection of regional ischemia are accomplished using low doses of MRI contrast media and multislice measurements in the cardiac short axis or along different axes of the heart.^{320, 321} With inversion recovery and gradient-echo planar imaging, an ischemic area is identified as a zone of either *low cold-spot* or *high hot-spot* signal, respectively (Fig. 33–15).^{320, 321, 341}

Signal intensity versus time curves is generally used for analysis of first-pass imaging studies. Different parameters can be calculated, including, for example¹⁸⁶:

1. The rate of signal intensity increase after bolus injection of contrast agent using a linear fit.
2. The maximum signal intensity increase.
3. The time from T_{null} to the maximum signal intensity value.
4. The signal intensity decrease after the peak signal intensity using an exponential fit.

Studies comparing the ability of MRI myocardial perfusion techniques to detect hypoperfused myocardial regions with thallium 201 (^{201}Tl) and technetium 99m ($^{99\text{m}}\text{Tc}$) radionuclide imaging and coronary angiography have shown sensitivity rates ranging between 64% and 92% and specificity rates between 75% and 100%.^{82, 120, 152, 333} Hartnell and colleagues showed an improved accuracy (similar to scintigraphy) when combining MR myocardial perfusion with cine MRI to detect associated wall motion abnormalities.¹²⁰ Wintersperger and coworkers compared myocardial perfusion with myocardial wall thickening in patients with chronic myocardial infarction.³³³ Wall thickening was significantly less in hypoperfused areas than in normally perfused areas. The location of hypoperfusion and restricted myocardial wall thickening correlated well. The combination of MR perfusion and cine MRI improved the sensitivity from 72% (using only MRI perfusion) to 100%, whereas the specificity decreased slightly (98% to 93%).

Several studies have stressed the advantages of MRI myocardial perfusion compared with radionuclide imaging to obtain information concerning heterogeneous (subepiendocardial, midendocardial, and subendocardial) transmural enhancement, which may reflect variability in myocardial perfusion across the wall.^{81, 328} Cherryman and colleagues studied 103 patients after their first acute myocardial infarction with ECG, echocardiography, ^{201}Tl single photon emission computed tomography (SPECT), and MRI perfusion.⁵³ They found that dynamic contrast-enhanced MRI was consistently better than TI-SPECT for detecting anterior septal and inferior posterior infarctions.

Several groups have used the myocardial perfusion reserve or myocardial perfusion reserve index to assess patients with coronary artery disease.^{1, 65, 327} The reserve index may be more reliable than determination of coronary flow reserve because the effect of (protective) myocardial collateral flow supply is taken into account. Al-Saadi and associates found a significant difference in myocardial perfusion reserve between ischemic and nonischemic myocardial segments (1.08 ± 0.23 and 2.33 ± 0.41 ; $P < .001$).¹ Using a cut-off value of 1.5, the diagnostic sensitivity, specificity, and accuracy for the detection of coronary artery stenosis ($\geq 75\%$) were 90%, 83%, and 87%, respectively. In a similar study by Cullen and colleagues, a negative correlation was found between the myocardial perfusion reserve index and percent coronary artery stenosis ($r = -.81$; $P < .01$).⁶⁵

Figure 33–15. Short-axis echo-planar acquisition from a 67-year-old man with a history of acute myocardial infarction. After intravenous administration of gadolinium (Gd-DTPA), the cavity blood of the right ventricle (RV) and the left ventricle (LV) has been opacified, as has the LV myocardium. Note the region of decreased contrast agent uptake (arrows), indicating previous infarction.

Functional Imaging in Ischemic Heart Disease

A major strength of MRI is its accurate assessment of ventricular function. Fast gradient-echo techniques provide high-contrast images with high temporal and spatial resolu-

tion that can be obtained within the time of a single breath-hold.⁷ This allows evaluation of regional myocardial contraction, ventricular filling and ejection, valve motion, and vascular flow patterns. Excellent visualization of the endocardial and epicardial surfaces of ventricular myocardium on cine MRI displays changes in wall thickening and wall motion throughout the cardiac cycle. The accuracy of measurements and reproducibility make cine MRI appealing as the preferred imaging modality for follow-up of patients.²⁷ Cine MRI can be used to accomplish the following^{6, 16, 128, 130, 225, 278, 324, 325}:

1. Determine regional and global sequelae of past myocardial infarction.
2. Detect ischemic myocardium in patients with coronary artery disease.
3. Differentiate between viable and nonviable myocardium in patients with chronic myocardial ischemia.
4. Measure myocardial mass.

These studies can be performed with the patient at rest or under stress.

Another unique capability of MRI is the use of myocardial tagging. A grid of tag lines is created noninvasively on the myocardium.^{9, 342} These tag lines track deformation of underlying myocardium through the cardiac cycle. Myocardial tagging can be used to perform, noninvasively, a myocardial strain analysis and to decompose gross wall deformation into more fundamental units of deformation, such as principal strains or fiber strains.^{26, 233} This technique has been used to depict functional recovery after thrombolytic therapy in infarcted myocardium,²⁵ to elucidate the mechanism of remote myocardial dysfunction,^{24, 27, 156, 158} to discriminate between viable and nonviable myocardium using stress myocardial tagging,⁶³ and to measure the efficacy of medication on left ventricular dysfunction (Fig. 33-16).¹⁵⁵ As a result of the need for computer-intensive postprocessing, the clinical use of MRI tagging is still limited.

Assessment of Myocardial Ischemia, Infarction, and Viability

Demonstrating the benefit of acute reperfusion intervention (i.e., thrombolysis, transluminal angioplasty, or immediate surgical revascularization) necessitates a technique for identification and quantification of infarct size and myocardium at risk at an early stage.²²⁷ In patients with chronic coronary artery disease and ventricular dysfunction, viable myocardium may persist in regions of chronic ischemic injury. Such myocardium may recover after revascularization and improve left ventricular function.

Proton Relaxation Times

The free water content of infarcted myocardium is related to the duration of the ischemic insult,^{138, 329} prolonging T1 and T2 relaxation times.^{93, 124} Regional differences in T1 and T2 relaxation times may be useful for differentiating normal myocardium from areas of necrosis.^{124, 323, 329} Differences in T1 relaxation are not clinically useful for infarct detection unless paramagnetic contrast agents are administered.

Wesbey and colleagues³²³ found a linear correlation between T2 relaxation time and the percentage of water content. Furthermore, infarcted tissues were visible as areas of increased signal intensity^{124, 253} on T2-weighted MRI sequences (Fig. 33-17). Many groups have used this approach to detect and quantitate myocardial infarctions.^{10, 46, 124, 129, 187, 195, 227, 253, 323} However, the relation between changes in relaxation times and the size and stage of myocardial infarction is complex^{40, 56, 213, 228, 265, 332, 334} and not completely understood.

Stress Imaging

Pharmacologic stress MRI using the β agonist dobutamine or the vasodilator dipyridamole¹⁷ offers an advantage in differentiating ischemic, stunned, or hibernating myocardium. Dobutamine is preferred because it offers the possibility of both low- and high-dose examinations needed for the differentiation of stunning versus ischemia.^{50, 304, 305} In general, analysis of regional endocardial motion, wall thickening, or absolute increase in wall thickness as parameters of regional systolic performance provides a sensitivity and specificity of 70% to 90%.^{1, 11, 14, 15, 153, 223, 224, 304, 305} These stress test results could be enhanced by the simultaneous evaluation of regional perfusion.^{82, 120} High-dose dobutamine MRI has been found superior to high-dose dobutamine stress echocardiography in detecting patients with significant coronary heart disease (>50% diameter stenosis).^{131, 210, 229}

Myocardial Wall Thickness and Dobutamine-Induced Wall Thickening

It is important to differentiate between left ventricular dysfunction caused by irreversible scar from that caused by viable but akinetic ventricular myocardium.¹¹² Chronic myocardial infarction is associated with myocardium less than 6 mm thick or the presence of focal aneurysm formation (Fig. 33-18). Moderate inotropic stimulation can transiently reverse postischemic myocardial dysfunction; these changes may be demonstrated by echocardiography or MRI. The high-contrast and spatial resolution of MRI resolves the epicardial and endocardial surfaces of the myocardium, thus allowing precise measurement of wall thickness. Baer and coworkers showed that viable myocardium is characterized by preserved end-diastolic wall thickness (>5.5 mm) and a dobutamine-inducible contractile reserve.^{12, 16} Both viability parameters reliably predict improvement in regional left ventricular function and ejection fraction after revascularization.¹⁶ Functional studies using cine MRI, performed at rest and during pharmacologic stress, can be performed during repetitive breath-holds and be completed with a contrast-enhanced study to evaluate delayed hyperenhancement in akinetic regions.²⁶²

Left Ventricular Failure

Left ventricular failure reflects the inability of the ventricle to pump blood and its ability to do so only from an abnormally elevated left atrial filling pressure.³³ It is frequently, but not always, caused by a systolic, contractile abnormality that results in a defect in the ejection of

Figure 33-16. Short-axis myocardial tagging in a 62-year-old man with an old inferoseptal myocardial infarction. *A*, End-diastolic (ED) short-axis image at the midventricular level, demonstrating normal-appearing left ventricle (LV) and right ventricle (RV). *B*, End-systolic (ES) image obtained at the same anatomic level. There is thickening of both the right and the left ventricular myocardium, but there is diminished thickening of the inferior interventricular septum (arrows). *C*, End-diastolic image obtained at the same anatomic level using myocardial tagging. *D*, End-systolic tagged image. The tag line (between arrows) running through the inferior interventricular septum remains straight, indicating a lack of intramyocardial motion.

blood from the heart. However, an abnormality in diastolic function may lead to abnormal ventricular filling, elevated left ventricular end-diastolic pressure, and elevated left atrial pressure. Rapid-onset diastolic failure may be caused by the decrease in compliance seen in acute myocardial ischemia.¹²³ More insidious onset may occur if chronically ischemic myocardium has been replaced by fibrous scar tissue.

Irrespective of the etiology of the left ventricular failure,

MRI is increasingly used in clinical trials to monitor the effects of pharmaceutical therapy on ventricular mass, volume, and ejection fraction. Because MRI techniques do not depend on geometric assumptions about the shape of either ventricle and are less operator dependent than echocardiography, they may be used for accurate and reproducible quantitation of ventricular volume and myocardial mass. The goal of medical therapy in heart failure is to reverse the inexorable dilatation and hypertrophy of the diseased

Figure 33-17. Short-axis images obtained from a 58-year-old man with an acute anterior myocardial infarction. A, T1-weighted image shows the normal appearance of the left ventricular (LV) and right ventricular (RV) chambers but a relative increase in signal intensity (arrows) of the interventricular septum and inferior LV myocardium. The papillary muscle (p) is labeled. B, T2-weighted image obtained at the same anatomic level exaggerates the increased signal intensity of the regional myocardial edema.

cardiac muscle. Serial calculations of the ventricular volume and myocardial mass, as well as the stroke volume and ejection fraction, provide an objective measure of the effectiveness of a medical therapeutic regimen.

Cardiomyopathy

MRI techniques allow direct demonstration of the ventricular myocardium. This provides a reproducible means of identifying the distribution of abnormal muscle and characterizing the nature of the abnormality. Cine acquisition displays the epicardial and endocardial borders of

the ventricular myocardium, providing temporally resolved imagery from which myocardial mass and ventricular chamber volumes and stroke volume can be computed. This provides a means of estimating ventricular function and allows monitoring the therapeutic response of medical or surgical intervention. Advanced tagging and phase-contrast acquisition techniques provide a means of investigating regional functional disturbance as well as myocardial blood flow.

Cine MRI is an excellent noninvasive technique used to diagnose cardiomyopathy and to distinguish between the three distinct forms of this disease. The clinical usefulness of MRI in patients with cardiomyopathy is reviewed in

Figure 33-18. A, End-diastolic (ED) horizontal long-axis gradient-reversal acquisition from a 64-year-old man with previous myocardial infarction. Poor definition and probable thinning of the distal anteroapical left ventricular (LV) myocardium (arrows) are demonstrated. LA, left atrium; RV, right ventricle. B, End-systolic (ES) image reveals increased left atrial (LA) size. The anteroapical myocardium is thin and also does not thicken.

terms of information obtained in each of the major categories: dilated, hypertrophic, and restrictive cardiomyopathy.

Dilated Cardiomyopathy

Dilated cardiomyopathy is characterized by ventricular dilatation, decreased contractility, as well as alterations in ventricular diastolic function.¹¹⁶ Cine MRI reliably quantifies ventricular volume and mass, ejection fraction, and wall stress in patients with dilated cardiomyopathy^{99, 276, 313} and may be used to monitor the functional status of the ventricle over time. The high reproducibility of cine MRI (with the variability in volume and mass measurements of < 5%)²⁷⁶ makes it an invaluable tool in the assessment of effects of medications. MRI was used to evaluate the response of patients with dilated cardiomyopathy to angiotensin-converting inhibitor therapy.⁷⁷

Analysis of cine acquisitions has revealed regional functional abnormalities in these patients not found in normal control subjects. The normal gradient in wall thickening, with gradual increase from base to apex, is absent in dilated cardiomyopathy, as demonstrated on short-axis cine MRI^{276, 277} (Fig. 33–19). Myocardial tagging techniques provide a means of quantitating regional changes in myocardial function, reflecting both regional stress-strain relationships, as well as the fibrous anatomy of the heart. Depressed strain values correlate with depressed chamber function. Both of these parameters were shown to be markedly decreased¹⁹² in patients with dilated cardiomyopathy, with preservation of fiber orientation throughout the cardiac cycle. These findings suggest that myocardial tagging may also be a useful tool for testing therapeutic regimens⁸⁵ in these patients.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy presents clinically with both diastolic and systolic dysfunction.²⁶⁸ The dramatically thickened ventricular myocardium in this family of diseases has a distinctive appearance on MRI. In these patients MRI allows a significantly more comprehensive evaluation of the diseased myocardium than does echocardiography.^{102, 230}

In patients with hypertrophic cardiomyopathy, MRI allows improved visualization of wall segments (97% of segments) as compared with the use of echocardiography (67% of segments).²³⁰ Regional hypertrophy found on MRI correlated with Q-wave abnormalities demonstrated by ECG, whereas the configuration of the T-wave reflected the distribution of hypertrophy between the basal and apical segments.²⁶⁴ Use of MRI allows accurate characterization of the distribution of apical hypertrophy; distribution can be described as symmetrical, asymmetrical, or only involving the cardiac apex²⁸¹ (Fig. 33–20). In a longitudinal study, MRI was used to demonstrate that the characteristic “spadelike” configuration of the left ventricular chamber may begin with a “nonspade” configuration.²⁹³

In patients with hypertrophic cardiomyopathy, cine MRI has been used to quantitate left ventricular mass, volumes, and ejection fraction as well as right ventricular function. Suzuki and colleagues²⁹² found increased right ventricular mass, reduced peak filling rate, and decreased right ventricular filling fractions in these patients. Velocity-encoded cine MRI has been used to study coronary sinus blood flow in patients with hypertrophic cardiomyopathy.¹⁴³ Resting coronary blood flow was not significantly different from that found in normal individuals. However, after dipyridamole administration, coronary sinus blood flow in patients with hypertrophic cardiomyopathy increased to a much lower level than that seen in the healthy volunteers, indicating decreased coronary flow reserve. Impaired diastolic function due to nonuniform hypertrophy with subsequent loss of myocardial contractile elements, myocardial perfusion abnormalities, and change in left ventricular geometry has been demonstrated.³³⁸

Using myocardial tagging, significant reduction in the wall motion of the hypertrophied interventricular septum has been shown.¹⁷⁴ Depressed circumferential segment shortening in the anterior and inferior regions of the interventricular septum¹⁵⁷ and impaired systolic wall thickening (related inversely to wall thickness)⁷⁸ have been demonstrated as well.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a family of diseases that is characterized by primary diastolic dysfunction with com-

Figure 33–19. MR image of dilated cardiomyopathy in a 59-year-old woman. *A*, End-diastolic (ED) short-axis image through the papillary muscles (arrows) shows mild dilatation of the left ventricle (LV) with relative preservation of the right ventricle (RV). *B*, End-systolic (ES) image reveals no regional wall motion abnormality but diminished contraction and relatively increased end-systolic cavity volume.

Figure 33-20. MR image obtained from a 17-year-old girl with hypertrophic obstructive cardiomyopathy. *A*, End-diastolic (ED) oblique axial-gradient reversal acquisition shows near-normal left ventricular (LV) size. The superior interventricular septum (arrow) is slightly asymmetrical with respect to the remainder of the LV myocardium. The right ventricle (RV), ascending (Ao) and descending (AoD) aorta, left atrium (LA), and right pulmonary artery (RP) are labeled. *B*, End-systolic (ES) image shows a dramatic difference in septal thickening, causing narrowing of the subvalvular left ventricular region. The mitral leaflets (arrows) are closed, and there is no mitral regurgitation.

plete or partial preservation of systolic ventricular function; it must be differentiated from pericardial constriction.²³¹ MRI is the study of choice in this circumstance, allowing both the characterization of the ventricular functional abnormality and demonstration of the pericardial abnormality.^{184, 273} Pericardial thickening greater than 4 mm indicates pericarditis underlying the restrictive symptoms and hemodynamic measurements.¹⁸⁴

Amyloidosis frequently causes restrictive cardiomyopathy. It may be recognized by widespread thickening of all chamber walls and atrioventricular valve leaflets in the face of decreased ejection fraction and abnormal segmental wall motion. When compared with patients with hypertrophic cardiomyopathy, patients with cardiac amyloidosis had enlarged right atria and increased right atrial and ventricular wall thickness.⁸⁴ Restrictive cardiomyopathy can be differentiated from hypertrophic cardiomyopathy on cine MRI, because the systolic function (ejection fraction and wall motion) is usually normal to increased in hypertrophic cardiomyopathy but reduced in amyloid heart.

Comparison of MRI findings in patients with amyloid infiltration, patients with hypertrophic cardiomyopathy, and normal volunteers demonstrated a significant decrease in myocardial signal intensity in patients with amyloid heart as opposed to the other two groups, possibly because of magnetic field heterogeneity and decreased proton concentration inherent in amyloid deposition. In addition, mitral and tricuspid regurgitation frequently associated with restrictive cardiomyopathy can be demonstrated and quantified on MRI.⁷⁵ In patients with cardiomyopathy due to cardiac sarcoidosis, loci of high myocardial signal intensity were found on T1-weighted images after administration of intravenous Gd.^{51, 246}

Myocarditis

Myocarditis is an inflammation of the myocardium associated with myocyte damage or necrosis. In the United

States viral etiology accounts for most cases, although it may also be due to chemical agents, local toxin production, as well as immune-mediated diseases. The symptoms are nonspecific, because patients frequently present with palpitations, malaise, shortness of breath, and chest pain or discomfort, and they can be mistaken for cardiomyopathy or coronary artery disease. Most patients recover, but a fraction will develop cardiomyopathy.³⁸ Some cases of sudden death after a viral illness are thought to represent sequelae of viral myocarditis.^{70, 98}

Myocarditis is often a clinical diagnosis, because the definitive diagnosis requires an endomyocardial biopsy. However, a myocardial biopsy is invasive and can be associated with severe complications. In addition, the focal nature of the disease leads to frequent nondiagnostic or false-negative results. Scintigraphy with indium 111 monoclonal antimyosin antibody²² and gallium 67³⁰⁷ used noninvasively to assess myocardial inflammation are limited by a high false-positive rate and frequent overestimation of the extent of myocardial damage.^{30, 207}

The early experience with MRI for evaluation of myocarditis suggested that T2-weighted and T1-weighted, Gd-DTPA-enhanced spin-echo sequences were useful.^{22, 52, 100, 188, 189} T2-weighted sequences showed increased signal in the affected muscle, probably due to myocardial edema, whereas Gd-DTPA T1-weighted sequences demonstrated enhancement of the damaged myocardial muscle. In a study of 19 patients with viral myocarditis,⁹⁷ Gd-DTPA-enhanced MRI was used to follow the course of the disease and to estimate the extent and distribution of myocardial involvement. Early in the course of the disease, myocardial enhancement tended to be localized, reflecting the focal nature of the myocardial inflammation. However, as the disease progressed, the enhancement was seen throughout the muscle, depicting an evolution of myocarditis into a diffuse process.

In a more recent study²⁵² a group of 20 patients was studied with Gd-DTPA-enhanced spin-echo and cine MRI; 12 had myocarditis, and 8 did not. In the group with myocarditis, wall motion abnormalities as seen on cine MRI matched exactly the regions of abnormal enhancement on Gd-DTPA spin-echo examinations. These authors concluded that in a correct clinical setting, focal myocardial enhancement strongly supports the diagnosis of myocarditis, especially when associated with regional wall motion abnormalities.

Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic right ventricular dysplasia is a cardiomyopathy of unknown etiology that is characterized by ventricular tachycardia originating in the right ventricle, ST changes in the right-sided precordial leads of the surface ECG, regional and global right ventricular contractile abnormalities, as well as thinning and fibrofatty replacement of the right ventricular myocardium.¹⁷⁸ Although severe right ventricular dilatation, reduced right ventricular ejection fraction, and right ventricular failure as well as left ventricular dysfunction have been reported,^{177a, 316} most individuals have localized or patchy areas of segmental right ventricular thinning and akinesia or dyskinesia and are minimally symptomatic. Differentiation between right ventricular dysplasia and pathologic fatty infiltration can be made on clinical and histologic grounds. Fatty infiltration usually does not cause clinical symptoms,³¹ whereas right ventricular dysplasia does. In addition, in right ventricular dysplasia, abnormal foci of fat extend from the epicardial surface through the interstitium, displacing myocardial fibers.¹⁶⁹

Right ventricular dysplasia appears to be inherited, with a strong familial tendency suggesting an autosomal dominant disorder with variable expression and penetrance.²¹¹ It is usually diagnosed in individuals between 20 and 50 years of age,⁶⁸ but it may be diagnosed in young persons^{221, 295} as well. The disease is found predominantly in men, and symptoms frequently occur with exercise. This condition must be differentiated from right ventricular outflow tract tachycardia,^{37, 139} which carries a significantly lower risk of sudden death. Pathologic changes of right ventricular dysplasia are similar to those found in Uhl's anomaly.

ECG-gated cine cardiac MRI is considered a useful means of assessing right ventricular free wall myocardial thinning and fatty infiltration, as well as global and regional wall motion abnormalities.^{8, 31, 243} In axial and short-axis section, the free wall of the normal right ventricle should appear as a relatively homogeneous, intermediate signal intensity extending from the fat of the anterior atrioventricular ring toward the anterior extension of the interventricular septum. There is usually a thin and tapering deposit of epicardial fat extending from the atrioventricular ring along its proximal surface, immediately subjacent to the pencil-thin line of the pericardial space.¹⁵⁹ The myocardium of the free wall is not always demonstrated in all sections because it is relatively thin and sometimes cannot be resolved spatially. The diaphragmatic right ventricular wall is best

viewed in short-axis section and should appear slightly thicker than the free wall but thinner than the interventricular septum.

In patients with right ventricular dysplasia, the shape and volume of the right ventricular chamber may appear normal or "dilated" to the eye. The right ventricular free wall myocardium may appear diffusely thinned or have loci of "absent" myocardium, representing local areas of marked thinning (Fig. 33-21). Furthermore, on T1-weighted images, loci of increased intramyocardial signal intensity, representing fatty infiltration, are observed in both the diaphragmatic and free wall. Although these changes may be identified with conventional body coil acquisitions, use of a dedicated cardiac or general purpose chest coil provides the most reliable demonstration of free wall myocardial changes. Care must be exercised to place the coil over the anterior aspect of the heart. The center of the coil should be applied about 5 cm to the left of midline, just medial to the nipple.

Use of gradient-echo acquisition for cine examination of the right ventricle in this condition may be helpful in identifying focal areas of free wall dyskinesia. In a similar but benign syndrome, right ventricular outflow tract tachycardia, focal right ventricular myocardial wall thinning or excavation, or wall motion abnormalities may be identified. However, they are restricted to right ventricular outflow tract, differentiating them from the findings in arrhythmogenic right ventricular dysplasia.⁴⁹

Magnetic Resonance Coronary Arteriography

All forms of MRI are exquisitely sensitive to motion and turbulent blood flow artifacts. Cardiac MRI is especially sensitive to cardiac and respiratory motion and arterial pulsation. MR coronary arteriography attempts to demonstrate vessels smaller than 5 mm in caliber running along the epicardial surface of the contracting heart. Clinical success has been mixed.

Conventional ECG-gated spin-echo (Fig. 33-22) and gradient-echo (Fig. 33-23) MRI usually demonstrate portions of the epicardial coronary arterial tree but cannot be relied on for precise morphologic diagnosis. Recent advances in fast MRI have nearly eliminated respiratory and cardiac motion artifacts; MRI may provide a noninvasive means of visualizing the epicardial coronary arteries. ECG-gated two-dimensional gradient-echo acquisition sequences depict laminar blood flow as bright signal and turbulence or absent blood flow as signal voids. Use of fat-suppression techniques increases the contrast of the epicardial coronary arteries by decreasing the relative signal produced by the epicardial fat surrounding the arteries (Fig. 33-24). In addition, rapid-acquisition sequences allow image acquisition during a single breath-hold with and without the use of k-space segmentation to provide rapid visualization of the epicardial coronary tree.^{79, 167, 176, 222, 331}

In a preliminary evaluation of k-space-segmented, fat-suppressed, single-breath-hold MR arteriography¹⁷⁶ in 25 subjects (including 19 healthy volunteers and 6 patients undergoing diagnostic coronary arteriography), the left main coronary artery (LMCA) was identified in 24 (96%)

Figure 33-21. Arrhythmogenic right ventricular dysplasia in a 36-year-old woman with syncopal episodes. *A*, Axial double-inversion recovery acquisition through the atrioventricular septum (long white arrow) and mitral valve. The heart is rotated into the left chest secondary to right heart dilatation. The right ventricular free wall myocardium cannot be visually distinguished from epicardial fat and appears thinner (black arrows) than that adjacent to the atrioventricular ring (indicated by the signal void of the right coronary artery (arrow-head). LA, left atrium; LV, left ventricle; RA, right atrium. *B*, End-diastolic (ED) gradient-reversal acquisition obtained at nearly the same anatomic level. *C*, End-systolic (ES) image demonstrates left and right ventricular myocardial contraction but failure of the abnormal free wall myocardium to thicken. Furthermore, the signal intensity (arrows) of this portion of the right ventricular myocardium is increased.

Figure 33-22. Incidental demonstration of the coronary arteries. *A*, Axial spin-echo acquisition obtained from a 52-year-old man with a history of a mediastinal mass. The origin and course of the left main coronary artery (short arrows) from the aortic root (Ao) as well as the proximal course of the anterior descending coronary artery (long arrows) are clearly seen. The right ventricular outflow tract (RVO), superior vena cava (SVC), right (RP) and descending left (LP) pulmonary arteries, and descending aorta (AoD) are marked. *B*, In this short-axis section, obtained for evaluation of pericardial thickening, almost the entire course of the right coronary artery (arrows) can be visualized by its contrast with surrounding fat. The left atrium (LA), the right atrium (RA), the posterior right aortic sinus of Valsalva (pr), the confluence of the right pulmonary artery (RP) and the left pulmonary artery (LP), and the left bronchus (LB) are identified.

Figure 33-23. Adjacent gradient-echo four-chamber views obtained from a 39-year-old man evaluated for heart failure. A, The origin of the left main coronary artery from the posterior left aortic sinus of Valsalva (pl) is clearly seen. As the artery (arrow) dips beneath the left atrial appendage (LAA), it moves out of plane and is cut off. The right atrium (RA), the right ventricle (RV), and the posterior right aortic sinus (pr) are labeled. B, Gradient-echo acquisition obtained 5 mm caudad to A. The circumflex coronary artery (arrows) is seen coursing along the posterior aspect of the left ventricle.

subjects. The left anterior descending coronary artery (LAD) and right coronary artery (RCA) were visualized in all 25 individuals. The left circumflex artery (LCx) was seen in 19 (76%). Diagonal branches of the LAD were identified in 20 (80%) subjects. In the 6 patients in this series with angiographically proven coronary artery occlusion, absence of signal distal to the area of occlusion was identified by MR coronary arteriography. In a similar

series,³³¹ 39 adults referred for diagnostic coronary arteriography also underwent single-breath-hold, gradient-echo MR coronary arteriography within 1 week of their conventional arteriograms. Conventional coronary arteriography demonstrated moderate to severe proximal coronary artery narrowing in 74% of patients. Overall sensitivity and specificity of MRI for correct identification of hemodynamically significant (>50%) stenosis was 90% and 92%, respectively. Sensitivity and specificity of the technique for the LMCA were both 100%, 71% and 90% for the LCx, and 100% and 78% for the RCA, respectively.

Duerinckx and Urman⁷⁹ reported a series of 20 patients undergoing both conventional and MR coronary arteriography. They found 50% sensitivity for stenosis of the LMCA, 73% sensitivity for stenosis of the LAD, 0% for the LCx, and 62% sensitivity for significant stenosis of the RCA (overall sensitivity, 63%). Specificity in this series was 84% for the LMCA, 37% for the LAD, 82% for the LCx, and 56% for the RCA. Similarly, Pennell and coworkers²²² reviewed this technique of MR coronary arteriography in a group of 21 healthy controls and 5 patients with angiographically proved coronary artery disease. Twenty-two (85%) of the 26 subjects were successfully imaged. The LMCA was identified in 95%, the LAD in 91%, the LCx in 76%, and the RCA in 95% of studies. All five coronary occlusions in their series were identified by MR coronary arteriography. Although most missed vessels occurred early in their series, imaging the circumflex artery was problematic throughout their experience.

Preliminary experience with three-dimensional gradient-echo MRI acquisition¹⁶⁷ provided similar findings. The proximal coronary tree was not identified in all subjects. The LMCA was identified in 4 (57%) of 7 healthy volunteers. In this same group of volunteers, the LAD was identified in 4 (57%) of 7, the LCx in 2 (29%), and the RCA in all 7 (100%). Seven patients studied by conven-

Figure 33-24. K-space-segmented, breath-hold, fat-saturated, short-axis, gradient-echo acquisition. The course of the right coronary artery from the anterior aortic sinus of Valsalva (a) is clearly visible as a result of the fat-suppressed anterior atrioventricular ring. The proximal segments of marginal branches of the right coronary artery (arrows) are visible. LV, left ventricle; PA, pulmonary artery; RA, right atrium.

tional coronary arteriography and MR coronary arteriography had 17 diseased arterial segments. MR coronary arteriography demonstrated altered signal intensity in 13 (76%) of these segments.

Administration of intravenous contrast material increases contrast between blood and the surrounding arterial wall. This improves the low signal-to-noise ratios inherent to k-space-sampled breath-hold acquisitions.^{108, 126, 149, 166, 237, 310, 343} In a report of the comparison of conventional x-ray angiography with intravenous contrast-enhanced breath-hold MR coronary angiography¹⁷⁷ in 50 patients with suspected coronary artery disease, 76.6% of arterial segments could be adequately analyzed. MR coronary angiography detected the presence of significant (>50%) stenoses and occlusions in 34 of 36 patients and excluded significant stenosis or occlusion in 8 of 14 patients. These workers found a sensitivity of 94.4%, a specificity of 57.1%, a positive predictive value of 85%, and a negative predictive value of 80% for this technique.

For MR coronary arteriography to become a useful modality in the evaluation and management planning of patients with coronary heart disease, it must first be able to reliably demonstrate the entire epicardial coronary tree. (Can one imagine the growth in use of coronary arteriography if it allowed visualization of only the proximal epicardial arteries in only 80% of cases?) MR coronary arteriography cannot as yet provide complete and reliable noninvasive demonstration of the epicardial coronary arteries and their branches. Needless to say, advances in pulse-sequence design, as well as hardware considerations (such as dedicated chest surface coils and higher RF gradients) will undoubtedly improve our ability to demonstrate the coronary arteries using MRI. We must ask whether our ability to demonstrate the coronary arteries per se improves our ability to diagnose coronary artery disease and identify patients at risk for future cardiac events. Then we must improve the sensitivity and specificity for the detection of less severe (<50%) luminal narrowing. Otherwise, the usefulness of MRI for detecting non-flow-limiting plaques, the major source of acute coronary occlusion and sudden cardiac events, will be limited. Furthermore, if MR coronary arteriography is to become a noninvasive replacement for conventional catheter coronary arteriography, then the sensitivity and specificity for detection of significant vessel stenosis must increase. Claims of MRI eventually providing combined morphologic and functional analysis of the heart do not obviate limited spatial resolution, difficulties in the sensitive and specific imaging of the posterior circulation and arterial side branches, as well as differentiation between coronary arteries and cardiac veins.

Magnetic Resonance of Valvular Heart Disease

It is unusual for MRI to be employed as the first imaging technique in the work-up of cardiac murmurs. Nevertheless, MRI yields important information concerning cardiac chamber size, myocardial mass, pulmonary blood flow, and pulmonary venous pressure in these patients. MRI may be useful for demonstration of the jets of valvular dysfunction, as well as the means of quantitating the dysfunction and

its sequelae. The response of the heart to valvular dysfunction leads to characteristic changes in chamber volume and myocardial mass to maintain myocardial wall stress and systemic cardiac output. Recognition of the morphologic changes as well as understanding the homeostatic mechanisms that lead to these changes forms the basis of cardiac diagnosis.

Mitral Stenosis

Congenital mitral stenosis is rare and is observed mainly in infants and children.²⁵⁰ Rheumatic mitral stenosis results from the chronic and progressive fibrotic process instigated by the initial rheumatic inflammatory reaction. The slowly progressive process of reactive fibrosis may take 20 to 40 years before a patient with a history of acute rheumatic fever develops signs or symptoms of rheumatic mitral stenosis. Once symptoms occur, another decade may pass before symptoms become disabling.^{255, 336} The mitral leaflets thicken, calcify, and fuse. The chordae tendineae become thickened, fused, and nonpliable. All of these changes cause decreased diastolic leaflet excursion and functional narrowing of the mitral orifice.^{250, 336} Isolated mitral stenosis occurs in about 40% of all patients presenting with rheumatic heart disease. Nearly 60% of patients with pure mitral stenosis give a history of previous rheumatic fever.^{256, 336}

In the early phases of mitral stenosis, elevated pulmonary venous pressure is transmitted across the capillary bed, resulting in "passive" pulmonary arterial hypertension. This may be identified as an increase in the caliber of the central pulmonary artery segments. However, pulmonary arteriolar resistance subsequently rises in these patients,^{110, 337} causing precapillary pulmonary hypertension. On spin-echo MR images (Fig. 33-25), increased pulmonary resistance may be reflected in slowing of pulmonary blood flow, resulting in increased signal within the pulmonary arteries. Chronic elevation in pulmonary resistance results in right ventricular hypertension and myocardial hypertrophy. On gradient-echo MRI (Fig. 33-26) acquisition, thickening of the right ventricular free wall or interventricular septum is evident. Furthermore, the hypertrophic response changes the geometry of the right ventricular cavity, changing the curvature of the interventricular septum. This is first reflected as straightening and subsequently as reversal of the systolic bowing of the septum toward the right ventricle. In addition, change in the geometry of the interventricular septum affects the function of the tricuspid valve papillary muscles, inducing tricuspid regurgitation. Therefore, mitral stenosis frequently presents as a complex lesion, affecting both atria and atrioventricular valves, as well as the right ventricle. Throughout the course of mitral stenosis, until late in the disease, the left ventricular volume, mass, and function remain normal.

Mitral Regurgitation

Acute, severe mitral regurgitation imposes a sudden volume load on an unprepared left ventricle. Although this acts to increase left ventricular stroke volume, forward

Figure 33-25. Axial spin-echo image of chronic rheumatic mitral stenosis in a 60-year-old man. Left atrial (LA) enlargement is associated with thickening and doming of the mitral leaflets (arrows), increased signal in the gravity-dependent posterior lung parenchyma (indicating interstitial edema), and a normal left ventricle (LV). The right atrial appendage (RAA) and the right ventricle (RV) are both mildly dilated.

stroke volume and total cardiac output are reduced; adequate time for development of compensatory eccentric left ventricular hypertrophy does not transpire. Similarly, the left atrium cannot accommodate the rapid increase in volume, so early systolic left ventricular ejection into the left atrium results in left atrial hypertension and pulmonary vascular congestion. Patients with acute mitral regurgitation commonly present with both low cardiac output and pulmonary congestion. Acute mitral regurgitation results from sudden changes in the chordae tendineae anchoring the

Figure 33-26. Diastolic axial gradient-echo acquisition from a 62-year-old man with chronic rheumatic mitral stenosis. Left atrial (LA) enlargement is seen in the presence of a normal left ventricle (LV). The jet of accelerating flow across the narrow valve orifice (arrows) is shown.

valvular leaflets or damage of the leaflets themselves. A good example is infectious endocarditis, which may present with both chordae tendineae rupture and leaflet perforation. Acute papillary muscle dysfunction or rupture of the head of a papillary muscle compromises the apposition of the valve leaflets. Myocardial infarction is a frequent cause of papillary muscle rupture, commonly resulting in severe congestive heart failure and, unless treated emergently, death. Acute myocardial infarction in muscle adjacent to a papillary muscle insertion may result in papillary muscle dysfunction and mitral regurgitation. Other causes of mitral regurgitation include mitral valve prolapse syndrome, acute and/or chronic rheumatic heart disease, and collagen vascular disease. An uncommon cause of mitral regurgitation is ingestion of anorectic agents.⁶⁰

When examined in the acute phase of mitral regurgitation, the most prominent findings are those of severe pulmonary congestion with nearly normal heart size. MRI often reveals the signal-void jet of mitral regurgitation, which appears as an early systolic fan-shaped signal void extending from the mitral annulus into the left atrium (Fig. 33-27). Left ventricular volume is not increased. Spin-echo examination may show normal left atrial size.

In cases of chronic mitral regurgitation, the initial insult may be minor and not sufficient to produce the signs and symptoms of low cardiac output and pulmonary congestion. Adequate time transpires for the ventricular myocardium to hypertrophy as well as for individual myocardial fibers to lengthen.^{47, 115} This compensatory increase in left ventricular end-diastolic volume permits increased total stroke volume and restoration of forward cardiac output.³⁴⁴ In an analogous manner, left atrial dilatation allows accommodation of the additional regurgitant volume at a lower left atrial pressure.

Figure 33-27. MR image demonstrating acute mitral regurgitation in a 52-year-old man suffering an acute myocardial infarction. Systolic oblique axial gradient-echo acquisition. A signal void jet (small arrows) extends from the mitral annulus into the normal-appearing left atrium (LA). Although left ventricular (LV) size is normal, the anteroseptal wall (large arrow) is aknetic. Ao, aorta; eff, pleural effusion; RV, right ventricle.

Figure 33-28. Spin-echo acquisition obtained from a 46-year-old woman with chronic mitral regurgitation. *A*, Coronal acquisition at the level of the origin of the left subclavian artery (arrows) from the aortic arch (Ao). The left atrium (LA) is markedly enlarged. The main pulmonary artery (MP) is no larger than the Ao, indicating normal pulmonary artery pressure. *B*, Sagittal section through the body of the dilated left ventricle (LV). T, trachea.

Chronic mitral regurgitation may result from the leaflet pathology, such as seen in myxomatous degeneration of the mitral leaflets (Fig. 33-28). In addition, secondary dilatation of the mitral orifice and loss of opposition of the mitral cusp edges due to alteration in the left ventricular geometry may also result in mitral regurgitation, as not uncommonly seen in dilated cardiomyopathy due to ischemic or hypertensive heart disease (Fig. 33-29). MRI evaluation of chronic mitral regurgitation does not demonstrate alveolar edema found in the acute phase. Rather, the dominant findings are those of left atrial and ventricular dilatation. As opposed to mitral stenosis, chronic mitral regurgitation is usually not associated with pulmonary hypertension. Right ventricular hypertrophy and right atrial and ventricular dilatation are not seen. MRI demonstrates left heart and pulmonary vein dilatation with normal or nearly normal left ventricular contractile function and the characteristic jet of mitral regurgitation (Fig. 33-30).

Aortic Stenosis

Aortic stenosis (see also the discussion on the bicuspid aortic valve in the section on congenital heart disease) can occur at, below, or above the aortic valve, that is, valvular, subvalvular, or supra-valvular stenosis. Regardless of the level of left ventricular outflow obstruction, all such lesions share the physiologic common denominator of increasing left ventricular myocardial strain, with the resultant formation of myocardial hypertrophy. The most common causes of aortic stenosis are congenital, calcific degenerative, and rheumatic disease.^{35, 206, 220} Subvalvular and supra-valvular aortic stenoses are usually congenital in origin.²⁴⁹

Figure 33-29. Axial spin-echo acquisition obtained from a 30-year-old man with hypertrophic obstructive cardiomyopathy being evaluated for a left atrial mass. Notice the thickened left ventricular (LV) myocardium, the dilatation of the left atrium (LA), and the entrance of the right lower lobe pulmonary vein (long arrow). The anterior mitral leaflet (short arrows) is displaced anteriorly from its posterior partner, resulting in mitral regurgitation. Incidentally, the questionable mass (M) is mesenteric fat in a sliding hiatus hernia immediately behind the left atrium. a, anterior aortic sinus of Valsalva; pr, posterior right aortic sinus of Valsalva; RA, right atrium; RV, right ventricle.

Figure 33-30. Axial gradient-echo acquisition from a 40-year-old woman with exercise intolerance and a history of previous left pneumonectomy for trauma. The heart is rotated and displaced into the left chest. The fan-shaped signal void (arrow) extends from the mitral valve into the left atrium (LA). The left ventricle (LV) is dilated. RAA, right atrial appendage; RP, right pulmonary artery; RV, right ventricle.

In congenital aortic stenosis, the aortic valve may be unicuspid or bicuspid. A unicuspid valve usually presents in the newborn period²⁰⁶ with critical left ventricular outflow obstruction and acute heart failure. MRI is rarely indicated in these patients. If performed, the major findings would be those of interstitial and alveolar pulmonary edema secondary to left heart failure. Calcification is rarely if ever evident this early in the course of any variant of aortic stenosis.

Although a congenitally bicuspid aortic valve is malformed at birth, it rarely causes a significant pressure gradient in infancy. In the early occult stages of the disease, the distorted leaflet architecture causes turbulent blood flow across the valve that traumatizes the leaflet edges, resulting in collagenous generation, lipid deposition, fibrosis, and calcification, similar to that found much later in life in individuals with stenosis of tricuspid aortic valves. Gradually, the leaflets become more rigid and the valve orifice narrows, resulting in a pressure gradient. The congenital malformation makes the valve more susceptible to infectious endocarditis, and this may result in aortic regurgitation.

Patients who present with signs and symptoms of aortic stenosis in middle age or later life usually have tricuspid aortic valves. Their valvular disease is the result of slow, progressive degeneration, calcification of the valve annulus and leaflets, and consequent narrowing of the effective valve area. This abnormality is thought to be the result of normal wear on the valve over a period of years. Hypercholesterolemia and diabetes are important predisposing factors for degenerative aortic stenosis. Commissural fusion is not usually seen in these patients.

Rheumatic aortic stenosis results in commissural adhesion and fusion, the hallmarks of the chronic rheumatic cycle of injury and healing. These aortic valves are frequently both regurgitant and stenotic, fixed in an open configuration. In long-standing cases of rheumatic aortic

stenosis, aortic valvular calcification may be found. This further narrows the valvular orifice. Concomitant mitral valvular disease is often present but may not be recognized clinically.

Other than in cases of congenital unicuspid aortic valve, the left ventricular obstruction develops gradually, resulting in increased left ventricular mass that increases wall thickness while maintaining normal chamber volume,^{263, 288} allowing the left ventricle to adapt to the systolic pressure overload. MRI reveals the thickened left ventricular myocardium in the absence of left ventricular dilatation. Furthermore, it is useful to demonstrate the abnormal architecture of a congenitally malformed valve.

In cases of valvular aortic stenosis, MRI demonstrates the poststenotic dilatation of the ascending aorta (Fig. 33-31). The aortic caliber is normal at the level of the annulus and increases to its maximum by the level of the transverse right pulmonary artery. The aorta then returns to normal diameter proximal to the arch. The aortic arch and descending aorta are usually normal in caliber. The shape and size of the signal-void jet, as well as its variable extension into the ascending aorta, depend on the shape of the orifice and the degree of its narrowing. The severity of the valvular gradient correlates with the size of the stenotic jet⁷¹ and its extension into the aorta.

If left ventricular outflow obstruction is subvalvular, such as in hypertrophic obstructive cardiomyopathy, then there is no poststenotic dilatation of the aorta. In these patients, however, systolic anterior motion of their anterior mitral leaflet results in mitral regurgitation. Membrane-like subvalvular aortic stenosis does not result in systolic anterior motion and mitral regurgitation. The association of left atrial enlargement (volume loading) with severe left ventricular hypertrophy (pressure loading) is characteristic of subvalvular aortic stenosis. MRI examination in these patients has an additional advantage of demonstrating the

Figure 33-31. Systolic axial gradient-echo acquisition from a 67-year-old man with chronic aortic stenosis. The signal void of accelerating left ventricular (LV) flow is seen as a fan-shaped jet extending from the aortic valve into the dilated ascending aorta (Ao). AoD, descending aorta; LA, left atrium.

Figure 33-32. Systolic oblique axial gradient-echo acquisition from a 26-year-old man with subvalvular aortic stenosis. Fan-shaped signal voids extend from the crest of the muscular interventricular septum (arrow 1) and the attachment of the anterior mitral leaflet (arrow 2) into the ascending aorta. The left atrium (LA) is normal, and the left ventricular (LV) myocardium is hypertrophied. RAA, right atrial appendage; RV, right ventricle.

predominately septal (or other asymmetrical) variant of myocardial hypertrophy (Fig. 33-32).

Aortic Regurgitation

Aortic regurgitation may be caused by disease of the aortic valve or of the aorta, which affects the valve. Valvular etiologies include rheumatic heart disease, infectious endocarditis, congenital bicuspid aortic valve, and Marfan's syndrome. Diseases of the aorta include trauma, aortic dissection, and idiopathic dilatation of the aortic annulus. Less commonly, inflammatory and connective tissue disease involving the aorta may result in aortic regurgitation.

Infectious endocarditis, acute aortic dissection, and thoracic trauma produce acute severe aortic regurgitation. This rapidly increases left ventricular filling pressure and reduces cardiac output. These patients often present in shock. Chronic aortic regurgitation causes slow, insidious left ventricular and aortic dilatation. Although dilatation may be pronounced, the function remains normal, and these individuals experience a prolonged asymptomatic phase of their disease.

The left ventricular response to aortic insufficiency depends largely on the rate at which the volume overload develops. Acute dilatation does not allow for ventricular adaptation, resulting in decreased forward cardiac output, elevated left atrial pressure, pulmonary edema, and shock. The value of MRI in patients with acute aortic regurgitation is in noninvasive demonstration of the underlying etiology for the acute left ventricular volume load (i.e., rib fractures and periaortic hematoma in acute aortic injury or the flap of an aortic dissection extending to the aortic valve).

Chronic aortic regurgitation is characterized by in-

creased left ventricular and aortic volume without increase in left ventricular pressure. Concentric and eccentric ventricular myocardial hypertrophy compensates for the increased wall stress induced by the regurgitant volume load. MRI quantitation of left ventricular mass showed that although left ventricular wall thickness may appear normal, myocardial mass does in fact increase in these patients. Thus, left ventricular performance (as reflected in normal ejection fraction) remains normal. With time, left ventricular dilatation is progressive and may become pronounced.⁴⁸ MRI demonstrates left ventricular and aortic dilatation (Fig. 33-33). The extent of the aortic dilatation varies with the severity and chronicity of the valvular dysfunction. MRI studies of these patients have the added advantage of direct demonstration of the jet of aortic regurgitation. Typically, this appears as an early diastolic signal void, seen along the anterior mitral leaflet, extending from the aortic valve to the back wall of the left ventricle but, depending on the shape of aortic valvular orifice, may be directed elsewhere in the left ventricle.

Most patients remain asymptomatic during this compensated phase, which may last for decades. Eventually, chronic left ventricular volume loading exceeds the increased contraction of the Frank-Starling mechanism, and the left ventricle begins to fail. MR examination in these patients exhibits the dilated left ventricle and aorta, with increased signal in the lungs resulting from interstitial edema. MRI may be useful for quantifying left ventricular diastolic volume and ejection fraction and for assessing ventricular function. In addition, long-standing aortic regurgitation may cause sufficient left ventricular dilatation to stretch the mitral annulus and induce mitral regurgitation, which in turn leads to left atrial dilatation (Fig. 33-34).

Tricuspid Regurgitation

Tricuspid regurgitation may be acquired or congenital, acute or chronic. This lesion may also be seen in individu-

Figure 33-33. Diastolic oblique axial gradient-reversal acquisition from a 38-year-old man with congenital aortic regurgitation. A broad signal void jet (J) extends from the aortic valve into the left ventricle (LV) along the anterior leaflet of the mitral valve (black arrows). The left atrium (LA) is normal. The right ventricle (RV), superior vena cava (SV), and proximal right coronary artery (white arrow) are identified. Ao, aorta.

Figure 33-34. Late diastolic oblique axial gradient-echo acquisition from a 70-year-old man with mixed rheumatic aortic and mitral regurgitation. Left ventricular (LV) and left atrial (LA) dilatation in the absence of apparent LV hypertrophy is seen. The signal void jets extend from the aortic valve into the LV (arrows 1) and from the mitral valve into the LA (arrow 2). RV, right ventricle.

als with a structurally normal valve. The most common cause of tricuspid regurgitation is pulmonary hypertension. Elevated right ventricular pressure, as seen in pulmonary hypertension of various causes, leads to right ventricular hypertrophy and alteration of shape of the interventricular septum. This distorts the function of papillary muscles originating from the septum, alters right ventricular geometry, and causes tricuspid annular dilatation,^{314, 315} all of which results in valvular incompetence.

Infectious endocarditis, carcinoid disease, rheumatoid arthritis, and trauma all may cause acute valvular (including tricuspid) regurgitation. Acute pancarditis of rheumatic heart disease leads to ventricular dilatation, whereas associated valvulitis results in laxity of the mitral and tricuspid annuli. Both lead to tricuspid regurgitation. The tricuspid valve leaflets in patients with Marfan's syndrome are floppy and redundant, which results in valvular regurgitation, often involving the tricuspid valve. Ebstein's anomaly^{164, 345} includes congenital malformation of the tricuspid valve, which causes varying and often severe tricuspid regurgitation.

No matter what the inciting event, initial tricuspid regurgitation volume loads the right atrium and right ventricle, resulting in their dilatation, which in turn alters right ventricular geometry, resulting in the vicious cycle of progressive valvular regurgitation.

Spin-echo and gradient-echo MRI sequences demonstrate the morphologic stigmata of tricuspid regurgitation. The right ventricle is normally found immediately behind the sternum. In patients with tricuspid regurgitation and other forms of right heart dilatation, the heart is rotated, displacing the right ventricle toward the left, and moving the right atrium to a position behind the sternum. There is

displacement of the superior vena cava medially, as well as clockwise rotation of the cardiac apex with horizontal (coronal) orientation and straightening of the interventricular septum. In severe cases, the interventricular septum bows to the left and may even extrinsically compress the left ventricle.

MRI demonstrates and accurately quantifies right ventricular myocardial hypertrophy. Furthermore, gradient-echo MRI demonstrates the signal void of the regurgitant jet (Fig. 33-35) directed toward the right atrium. Although the direction of the jet depends on the geometry of the valve and its deformity of the leaflets, it is always seen early in systole.

Differential diagnosis of tricuspid regurgitation depends on observation of coexisting findings. Tricuspid regurgitation caused by pulmonary hypertension is associated with dilatation of the right heart, the main pulmonary artery segment, and central hilar pulmonary arteries. Spin-echo MRI demonstrates increased signal in the pulmonary artery segments caused by the slow blood flow in patients with high pulmonary resistance. Left atrial enlargement and evidence of pulmonary hypertension in the face of a normal left ventricle point to mitral stenosis as a cause of the pulmonary hypertension and subsequent tricuspid dysfunction. Increased lung volumes and a normal left atrium suggest chronic obstructive pulmonary disease as the cause of the pulmonary hypertension. Patients with primary right heart failure exhibit right heart dilatation, pleural and pericardial effusion, and evidence of right atrial hypertension, including dilatation of the inferior and superior venae cavae, coronary sinus, hepatic veins, and azygos vein. Finally, right-sided heart enlargement with a small pulmonary artery indicates the decreased right ventricular output found

Figure 33-35. Systolic axial gradient-echo acquisition from a 24-year-old woman with primary pulmonary hypertension. The right ventricle (RV) is dilated, and the RV free wall myocardium is as thick as the interventricular septum. The signal void jet (arrows) of tricuspid regurgitation extends from the tricuspid valve into the dilated right atrium (RA). The right heart dilatation has rotated in a clockwise manner into the left chest. LV, left ventricle.

in patients with Ebstein's anomaly. All these findings are accurately demonstrated on MRI.

Multivalvular Heart Disease

In combined valvular heart disease, the dominant physiologic alteration, and thus, the clinical and radiologic picture, is determined by the proximal lesion. However, the radiologic appearance varies, depending on the relative severity as well as the physiologic sequelae of each particular valve lesion. The most common cause of multivalvular heart disease is rheumatic. The most common combinations are mitral stenosis with aortic regurgitation, mitral stenosis with tricuspid regurgitation, combined mitral and aortic regurgitation (see Fig. 33–34), combined mitral and aortic stenosis, and combined aortic stenosis and mitral regurgitation.

Quantitative Magnetic Resonance Imaging of Valvular Disease

Accurate estimation of the severity of a valvular lesion is crucial for timing surgical intervention. MRI provides an accurate, reproducible, noninvasive approach to quantification of valvular stenosis and regurgitation, cardiac chamber size, and myocardial mass and function. At present, valvular lesions suspected clinically or suggested on chest radiography are initially evaluated by Doppler echocardiography, followed by cardiac catheterization. Both these methods are semiquantitative and dependent on hemodynamic and technical factors.^{62, 258} Valvular regurgitation can be determined by nuclear ventriculography.^{144, 245} However, in addition to the drawback of radiation, this technique is influenced by multiple variables, such as the risk of superimposition of the cardiac chambers, the uncertainty of the chamber depth, and the difficulty of quantitation in the face of multiple regurgitant valvular lesions.

The pressure gradient across a valve can be indirectly quantitated using the modified Bernoulli equation.¹²⁷ In the early phase of valve disease this may be useful. However, later in the course of the disease, when cardiac output decreases, the technique becomes less accurate.¹¹⁴ Valve area and cardiac output can be assessed by planimetric analysis of conventional angiocardiology and Doppler echocardiography,^{182, 280} and cardiac catheterization,¹¹¹ although these techniques also have many limitations.^{20, 42}

Cardiac chamber volume can be estimated from spin-echo images. However, accurate measurement of end-systolic and end-diastolic volumes is required for calculation of cardiac output and stroke volume. These values can be reliably obtained only with MRI sequences capable of high-spatial-frequency resolution, such as cine gradient-echo imaging.¹¹⁹ Furthermore, breath-hold sequences allow a substantial reduction in both imaging time and motion artifacts.^{133, 259}

Imaging the ventricles in short-axis section minimizes volume-averaging artifacts. Subsequently, end-diastolic and end-systolic images are selected at each anatomic level. To calculate the end-systolic volume, the areas of the ventricular cavity are measured at end-systole for each level,

summed over the entire ventricular mass and multiplied by the slice thickness. The same procedure is repeated for the end-diastolic images, giving the end-diastolic volume. Similarly, the ventricular myocardial volume (which allows estimation of the myocardial mass) is calculated as the sum of the differences between epicardial minus endocardial areas times slice thickness, summed over the entire ventricle.

The prognostically relevant parameters such as stroke volume and ejection fraction, are calculated from the end-systolic and end-diastolic volumes. Extensive research culminated in validation of MRI as an accurate and reproducible method for determining ventricular dimensions and function.^{64, 141, 180, 181, 201–205, 298} At present, MRI is considered the clinical gold standard for determination of stroke volume, ejection fraction, myocardial volume (or mass), as well as ventricular volumes.

The reproducibility of ventricular volume measurements is further underscored by the small difference in the right and left ventricular volumes (<5%)^{170, 172, 270} in the absence of valvular regurgitation. Therefore, in patients with a solitary insufficient valve, the regurgitant volume and fraction can be calculated as a difference between and the ratio of the right and left stroke volumes.^{269, 298}

Direct measurement of chamber stroke volume, regurgitant volume, and regurgitant fraction can be performed using a velocity mapping technique, based on the linear relationship between the velocity of the spins along the magnetic field gradient and their phase shift. This promising technique provides accurate results in the presence of laminar flow patterns but is detrimentally affected by the complex, turbulent flow patterns^{88, 335} inherent in valvular heart disease. Recent advances have been made in reducing the influence of the complex flow patterns on the overall accuracy of this technique by decreasing the duration of the magnetic gradient field used for velocity encoding.^{150, 282, 284} These pulse sequences were validated in vivo.

In patients with aortic regurgitation, velocity encoding MRI acquisitions may be used for calculating left ventricular stroke volume, as well as regurgitant volume and regurgitant fraction. In these patients, positioning of the imaging plane close to the aortic valve is crucial for accuracy, because the results are heavily influenced by the coronary blood flow and aortic compliance. When these pitfalls are kept in mind, the accuracy rate of this technique is higher than 90%.²⁸³ Clinical relevance of these data is reflected in the usefulness of MRI evaluation of vasodilator therapy in patients with aortic regurgitation.¹⁰⁷ The transvalvular pressure gradient in aortic stenosis may be calculated from the peak velocity across the stenotic valve with accuracy that is higher than 85%.²⁸³ The valve area may be demonstrated by velocity encoding with an accuracy rate that is higher than 81%. The accuracy rate of quantifying the regurgitant volume and fraction in mitral regurgitation was reported as 91% and 94%, respectively, whereas in mitral stenosis the transmural peak velocity across the valve was calculated with an accuracy rate higher than 87%.²⁸³

Right Ventricular Disorders

Right ventricular disease may be difficult to evaluate by conventional echocardiographic and angiographic means.

Patients with chronic pulmonary disease commonly present with hyperaerated lungs and chest wall deformities, which limit the use of ultrasonographic methods. The high association of chronic heart disease, pulmonary disease, and pulmonary hypertension increases the risk of contrast right ventriculography or pulmonary arteriography in this population. MR image acquisition is not limited by pulmonary or chest wall disorders, and contrast administration for MRI evaluation of the right heart has always been interesting but may simply not be necessary.

Right ventricular function is commonly affected by disorders of the left-sided cardiac structures and the lungs. The most common cardiac causes for right ventricular dysfunction are chronic left ventricular ischemia and rheumatic mitral valve disease. Pulmonary diseases causing right ventricular dysfunction include chronic obstructive pulmonary disease and chronic interstitial diseases (i.e., idiopathic pulmonary fibrosis and cystic fibrosis). Chronic pulmonary vascular pathology, including chronic thromboembolism and primary pulmonary hypertension, also have a significant effect on right ventricular performance.

Common to all of these diseases is elevation of pulmonary vascular resistance with a commensurate increase in right ventricular pressure, resulting in right ventricular hypertrophy. Eventually right ventricular dilatation, tricuspid regurgitation, and right ventricular failure supervene. MRI provides direct, noninvasive visualization of the right ventricular chamber as well as the myocardium itself, allowing reliable demonstration of morphologic changes in the size and shape of the ventricle, thickness of the myocardium, and presence of abnormal infiltration by fat or edema. Furthermore, MRI is well suited for accurate and reproducible quantitation of right ventricular volume and myocardial mass.

Both the left and right ventricles share the interventricular septum. Thus, the septum acts as an "interface" between the left and right hearts. Right-sided heart disease impacts on left ventricular function, and vice versa, via the septum. Normally, the septum acts as if a part of the left ventricle. Viewed in short axis (see Fig. 33-19A and B), the wall segments of the left ventricle, including the interventricular septum, appear to contract radially and symmetrically during systole. The curvature of the interventricular septum is convex toward the right ventricular cavity during both ventricular diastole and systole. Changes in right ventricular shape bow the interventricular septum at the expense of left ventricular shape. That is, right ventricular dilatation may straighten, or even reverse, the contour of the interventricular septum toward the left ventricle (see Fig. 33-3). In such cases, left ventricular filling and thus end-diastolic volume may be impaired, limiting left ventricular output.

The most common cause of right-sided heart failure is chronic left-sided heart failure.²⁹⁶ The common denominator of this and other left-sided heart problems causing right ventricular dysfunction is chronic left atrial hypertension. That is, the left and right hearts also "communicate" across the pulmonary vascular bed. Pulmonary hypertension and right ventricular failure in patients with mitral stenosis are caused by back-transmission of elevated left atrial pressure and pulmonary arteriolar constriction. Pulmonary arteriolar constriction leads to more severe pulmonary hypertension

and right ventricular failure.^{275, 336} Chronic mitral stenosis results in severe pulmonary hypertension and right ventricular hypertrophy and, ultimately, right ventricular dilatation and failure. With time, severe pulmonary hypertension results in tricuspid as well as pulmonary insufficiency, further exacerbating the right ventricular failure. The pulmonary hypertension found in chronic mitral stenosis is more commonly found and is generally more severe than that found in chronic left ventricular ischemia. Treatment of the underlying mitral valve disease by mitral valve replacement results in a marked decline in pulmonary vascular resistance and pulmonary artery and right ventricular pressure.³⁴

Other, less common causes of chronic left atrial outflow obstruction and pulmonary venous hypertension include left atrial myxoma¹²² or thrombus,²⁹⁴ congenital mitral stenosis,⁵⁹ and cor triatriatum.²¹⁶ In the latter condition, there is a congenital membrane interposed between the pulmonary veins and the body of the left atrium. Depending on the caliber of the membrane orifice, a pressure gradient exists between the pulmonary veins and mitral valve. Thus, one finds elevated pulmonary venous pressure in the face of normal left atrial pressure. Acquired pulmonary veno-occlusive disease is an uncommon condition that usually presents in children and young adults.³¹¹ Pulmonary venous obstruction causes elevated pulmonary vein pressure and pulmonary resistance in the face of normal left atrial pressure, resulting in pulmonary hypertension with varying degrees of right ventricular failure.

Similar cardiac changes may be found in cor pulmonale, the syndrome of right ventricular hypertrophy, dilatation, and failure resulting from pulmonary hypertension secondary to lung disease.⁵⁷ Although this condition may be acute, as seen in sudden, massive pulmonary thromboembolism,^{67, 193} it most often develops chronically, resulting from hypoxia-induced pulmonary arteriolar vasoconstriction or fibrosis of the pulmonary vascular bed.^{90, 91} The basic components of cor pulmonale are increased pulmonary vascular resistance, pulmonary hypertension, and right ventricular hypertension.

Pericardial disorders, namely cardiac tamponade and pericardial constriction,¹⁶³ commonly result in acute and chronic diastolic right ventricular dysfunction, respectively. Although restrictive cardiomyopathy may initially present with right ventricular failure, it generally involves both left and right ventricles. These conditions are discussed in detail earlier in the chapter.

Not only does MR examination allow direct demonstration of the appearance and intraluminal flow characteristics of the pulmonary arteries,^{43, 89, 109, 190, 232, 308} it also allows detailed visualization of the shape and internal morphology of the right ventricle.^{23, 94, 180} Patients with cor pulmonale typically present with a massively dilated and hypertrophied right ventricle. Both the chamber volume and the myocardial mass are increased. Morphologic examination of the heart in these patients demonstrates thickening of the right ventricular myocardium, bowing of the interventricular septum toward the left ventricular chamber, and clockwise rotation of the cardiac apex on axial MR images (Fig. 33-36). Spin-echo images reveal morphologic changes of underlying disease, such as narrowed valve orifices, or thickened valve leaflets. Functional gradient-echo cine images may reveal the characteristic signal voids

Figure 33-36. MR image obtained from a 6-year-old girl with primary pulmonary hypertension and right ventricular dysfunction.

A, Axial spin-echo acquisition through the pulmonary arteries. The main pulmonary artery (MP) and both left (LP) and right (RP) pulmonary arteries are dilated and show increased signal intensity distally. Note how these mediastinal structures have been displaced toward the left chest by right heart dilatation. Ao, aorta.

B, End-diastolic (ED) short-axis section through the mid-interventricular septum. Note how the dilated right ventricle (RV) causes straightening of the interventricular septum (arrows), indicating diastolic RV volume loading (secondary to associated tricuspid regurgitation). LV, left ventricle.

C, In this end-systolic (ES) frame obtained at the same anatomic level as in **B**, there is reverse bowing of the interventricular septum, indicating systolic dysfunction. Although the right ventricular free wall myocardium is not clearly seen in **B**, it appears thicker than the interventricular septum and posterior left ventricular wall.

caused by mitral stenosis or tricuspid or pulmonary insufficiency.

Pulmonary Disease

Cor pulmonale results from chronic hypoxia or pulmonary vascular occlusion or both. Chronic obstructive and restrictive lung diseases lead to cor pulmonale due to chronic hypoxia. The most common parenchymal lung disease resulting in cor pulmonale is chronic obstructive airway disease.⁹⁰ Small airway obstruction results in decreased vital capacity and nonuniform distribution of inspired oxygen. Pulmonary arteriolar vasoconstriction leads to local hypoxemia, which initiates a vicious cycle of increased pulmonary arterial resistance and right ventricular failure. In patients with pure emphysema, parenchymal

destruction leads to reduction in the cross-sectional area of the vascular bed, resulting in further increase in pulmonary resistance. Typically, patients with emphysema develop cor pulmonale late in their clinical course.³⁹ There is a loose correlation between increased right ventricular mass^{66, 200} and emphysema symptoms. In one study, all individuals with clinical evidence of cor pulmonale had depressed right ventricular ejection fraction.²¹ A similar clinical picture is found in patients with asthma, chronic bronchitis, and cystic fibrosis. Right ventricular failure is a common complication of cystic fibrosis.¹⁴⁵ Nearly one third of patients who die with this diagnosis exhibit overt signs of right-sided heart failure within the last 2 weeks of life.²⁸⁹

Interstitial lung disease impairs oxygen diffusion. Progressive interstitial lung disease causes thrombosis and fibrous organization and a decrease in the cross-sectional area of the pulmonary vascular bed.^{90, 91} Pulmonary arterial

hypertension is commonly seen in patients with chronic interstitial pneumonia; advanced sarcoidosis and hemosiderosis²¹⁵; and pulmonary fibrosis secondary to collagen vascular diseases, such as rheumatoid arthritis,⁹⁶ dermatomyositis,¹³² and progressive systemic sclerosis.^{257, 260, 291, 299}

Pulmonary vascular occlusive diseases result in a reduction in the cross-sectional area of the pulmonary vascular bed, which causes increased pulmonary resistance, pulmonary hypertension, and right ventricular hypertrophy. Clinical pulmonary thromboembolism is a complication of lower extremity or pelvic deep vein thrombosis.^{61, 78a, 121} Silent pulmonary emboli are a relatively common phenomenon.¹⁷¹ These pulmonary emboli are usually small and occlude only a small portion of the pulmonary arterial bed without eliciting symptoms. These minute thromboemboli lodge in the peripheral branches of the pulmonary arterial tree over a period of many years, resulting in increased pulmonary resistance and arterial pressure. The multiple pulmonary vascular obstructions found in chronic pulmonary thromboembolism²⁰⁹ are different than the obstructing thrombi found in acute pulmonary embolism. A massive, acute pulmonary embolus must occlude more than half the pulmonary arterial bed before hemodynamic changes and clinical symptoms develop. However, in patients with recurrent thromboembolism, there frequently is underlying pulmonary hypertension. In this population, additional occlusion of a smaller portion of the pulmonary arterial tree has a hemodynamically significant effect. If pulmonary hypertension has existed for some time, the right ventricle undergoes compensatory hypertrophy to maintain adequate cardiac output in the face of the elevated pulmonary vascular resistance. Faced with sudden increase in arterial resistance due to an additional, large pulmonary embolus, the hypertrophied right ventricle cannot maintain adequate cardiac output. In chronic, recurrent pulmonary thromboembolism, emboli lodge repeatedly in the pulmonary arterial tree over a period of years. These patients experience neither pulmonary infarction nor sufficient acute occlusion of the pulmonary vascular bed to cause acute right ventricular failure. Rather, they experience a gradual occlusion of the pulmonary arterial bed accompanied by a progressive increase in pulmonary vascular resistance. Thus, time is available for right ventricular adaptation.

Primary pulmonary hypertension is a rare, progressive disease of unknown etiology^{244, 312} characterized by obstructive changes at the level of the precapillary pulmonary arterioles or pulmonary veins and venules. Progression of the disease and clinical deterioration are associated with decreasing right ventricular function.

Right ventricular enlargement of any etiology causing tricuspid annular dilatation results in tricuspid regurgitation. Pulmonary hypertension is the most common cause of tricuspid regurgitation, which increases the preload as well as the afterload on the right ventricle. Tricuspid regurgitation not only results in further right ventricular and right atrial dilatation but also increased right atrial pressure. This has a deleterious effect on right ventricular function by limiting right ventricular myocardial perfusion. Elevated right atrial pressure is transmitted into the coronary sinus. Thus, the difference between aortic diastolic pressure and coronary sinus pressure (the right ventricular myocardial

perfusion gradient) is decreased, causing right (and left) ventricular myocardial ischemia and systolic dysfunction.

Cardiac Tumors

Cardiac tumors are rare. They tend to grow slowly, and patients present with signs and symptoms caused by the tumor's distortion of adjacent structures or organs. Although it may be difficult to characterize a particular tissue origin from MRI, these examinations are extremely helpful for characterization of tumor morphology, evaluation of adjacent and distal structure involvement, and the effects of the tumor on cardiac function. The most common cardiac tumors are metastatic malignancies. These lesions reach the heart by direct extension from the lungs and breast. In autopsy studies, metastatic foci of melanoma is commonly found in the heart but is frequently not clinically important. MR examination is helpful for demonstrating extension of such masses through the pericardium to involve ventricular myocardium. Such information is important for evaluation of surgical resectability¹⁷³ of such masses.

Three fourths of all primary tumors of the heart are benign and of soft tissue origin,¹⁹¹ including rhabdomyoma, fibroma, lipoma (Fig. 33–37), angioma, and myxoma. These tumors generally appear as infiltrating masses with signal intensity characteristic of the tissue of origin, that is, high-signal lipoma and intermediate-signal-intensity rhabdomyoma. Differentiation of these benign masses from their sarcomatous counterparts can be inferred by identification of a high-signal-intensity necrotic core, or other evidence of hemorrhage, distant metastasis, or extensive pericardial and pleural effusion. Myxoma (Fig. 33–38) is the most common benign cardiac mass found in all age groups. It can occur at any time, but more than half of the patients are in their 4th, 5th, and 6th decades. Twelve

Figure 33–37. Axial spin-echo acquisition from a 35-year-old woman with a myocardial lipoma presenting as an unusual contour on the left heart border of a plain chest film. The high-signal-intensity mass (M) is isointense with subcutaneous and breast fat and infiltrates the posterior left ventricular (LV) wall. No pericardial or pleural effusion is seen. RA, right atrium; RV, right ventricle.

Figure 33-38. Coronal contrast-enhanced gradient-echo image obtained from a 54-year-old man admitted with a cold left lower extremity. The large filling defect of the atrial myxoma (M) is seen within the mildly dilated left atrial (LA) cavity. The normal appearance of the pulmonary artery (PA) indicates that there is no pulmonary hypertension. Ao, aorta.

percent of the Armed Forces Institute of Pathology series¹⁹¹ were older than 70 years of age. Three fourths of all myxomas originate in the left atrium, mostly attached to the interatrial septum in the region of the limbus of the fossa ovalis. Myxomas may be highly vascular and enhance with intravenous contrast agent administration.

Benign cardiac tumors are usually of intermediate, but homogeneous, signal intensity. Areas of increased signal intensity may represent areas of focal hemorrhage, indicating tumor necrosis, or deposits of fat, reflecting tissue inhomogeneity. Most benign tumors may be “peeled away” from the heart at operation. However, both benign and malignant lesions usually appear to infiltrate adjacent ventricular myocardium. Lipomatous hypertrophy of the interatrial septum (Fig. 33-39) is not truly a malignancy, but rather it is a collection of large fat deposits. It may be isolated to the interatrial septum or may extend along the lateral aspect of the right atrium into the right ventricle. Application of fat saturation during image acquisition may directly characterize the lesion.⁴

Malignant cardiac tumors are usually metastatic. About 10% of patients with malignant neoplasms have cardiac metastases. Clinical dysfunction is usually caused by pericardial involvement. This may be visualized as pericardial effusion, pericardial thickening, or both. Pericardial effusion may be serous or hemorrhagic. The most common metastasis in men is from lung; the most common in women is from breast (Fig. 33-40). These are followed by leukemia and lymphoma (Fig. 33-41). Cardiac involvement is often accompanied by involvement of other organs. Primary cardiac malignant tumors are mostly angiosarcoma, rhabdomyosarcoma, mesothelioma, and fibrosarcoma. Malignant tumors in children are rare. Pericardial involvement is usually found.

Figure 33-39. Axial spin-echo acquisition from a 59-year-old man with shortness of breath. There is marked deposition of material (M) isointense with the pericardial and subcutaneous fat. The mass extends from the interatrial septum into the right atrium (RA). LA, left atrium; LV, left ventricle; RV, right ventricle.

Magnetic Resonance Imaging of Congenital Heart Disease

Although gradient-echo (cine) technique is invaluable for evaluation of cardiac function, the increased contrast resolution of spin-echo techniques makes them the work-

Figure 33-40. MR image obtained from a 32-year-old woman 3 years after mastectomy for adenocarcinoma of the right breast, now complaining of shortness of breath. Nearly the entire right ventricle (RV) is filled with a homogeneous intermediate-signal-intensity mass (M1). The left ventricle (LV) is extrinsically compressed by the mass. In addition, there appears to be a locus of similar material (M2) contained within the pericardial space anterior to the heart. A small posterior pericardial effusion (e) is seen as well. RA, right atrium.

Figure 33-41. MR image obtained from a 16-year-old child with lymphoma. A, Coronal spin-echo image obtained through the ascending aorta (Ao) and main pulmonary artery (PA). A bulky, homogeneous, intermediate signal intensity mass is seen along the superior right cardiac border that involves the pericardial space (*arrow*) but seems to spare the right atrium. LV, left ventricle; M, mass; RA, right atrium. B, Axial spin-echo acquisition through the superior aspect of the right atrium and aortic valve. The paracardiac and pericardial components of the mass (M) are again seen. In this image, however, there is nodular involvement (*short arrows*) within the right atrium as well as infiltration of the interatrial septum (*long arrow*).

horse for morphologic evaluation by MR. In cases of congenital heart disease, cine acquisition supplements the anatomic and morphologic information obtained from spin-echo acquisitions. Increased spatial resolution is obtained by decreasing the field of view. Infants and small children may be examined from within a head-imaging coil; this allows thinner slice selection as well as a smaller field of view.

The difference in appearance between pediatric and adult patients with congenital heart disease reflects the hemodynamic alterations of the underlying malformation, the duration of the lesion, and the effects of superimposed acquired cardiovascular disease. Depending on the stage in the natural or “unnatural” (i.e., surgically palliated) history of the disease in which examination is performed, the sequelae and complications of the underlying disease may be different. For example, in an atrial septal defect in a child or adolescent, changes of right ventricular hypertrophy and pulmonary hypertension are usually absent. By the age of 45 years, pulmonary hypertension and right ventricular hypertrophy are to be expected. Furthermore, in the older population, altered left ventricular function and its effect on right ventricular function become issues for examination.

Atrial Morphology and Situs

The segmental approach to diagnosis^{300, 302} accurately describes congenital heart lesions and is readily applied to interpretation of static and cine tomographic images obtained from cardiac MRI examination. The premise of the segmental approach is that the three cardiac segments (atria, ventricles, and great arteries) develop independently.

By localization and characterization of each of the three cardiac segments and evaluation of the atrioventricular and ventriculoarterial connections and associated anomalies (such as shunts and valve atresia), congenital heart lesions may be diagnosed in a consistent and coherent manner. The usefulness of MRI¹¹⁷ lies in its ability to demonstrate characteristic morphologic findings needed to name the cardiac chambers, allowing characterization of atrial situs and atrioventricular and ventriculoarterial connections.

The morphologic right atrium (Fig. 33-42) is characterized as the atrial chamber that receives the hepatic venous drainage and the inferior vena cava. It possesses the right atrial appendage and the crista terminalis. The right atrial appendage is a broad-based, triangular-shaped extension of the atrial cavity (a trabeculated “pita pocket”). It is contained within the pericardium and lies anteriorly, medial to the right heart border. The crista terminalis is a fibrous remnant of the valve of the embryologic sinus venosus.¹⁹⁷ It divides the right atrial chamber into a smooth posterior portion and a moderately trabeculated anterior portion (including the appendage). The morphologic left atrium contains the left atrial appendage, which is long and narrower than the right atrial appendage (Fig. 33-43). It passes just inferior to the main pulmonary artery along the left of the heart to reach the radiographic left heart border. The walls of the left atrium are quite smooth; there is no crista terminalis. The left atrium usually receives the pulmonary veins (except in partial or total anomalous pulmonary venous return).

Atrial situs may be directly determined by analysis of the appearance (morphology) of the atria.¹⁰⁵ Alternatively, situs may be deduced from the situs of the lungs (Fig. 33-44). In the normal individual in situs solitus, the mor-

Figure 33-42. Axial spin-echo acquisition from a 6-year-old boy at the level of the aortic root (Ao) and the right ventricular outflow tract (RVO). The characteristic trabeculations of the right atrial appendage (arrows) and the wide orifice adjacent to the entry of the superior vena cava (SV) are shown. The high-signal-intensity crista terminalis (long arrow) is viewed in cross-section. LA, left atrium.

Figure 33-44. Coronal spin-echo acquisition through the tracheal bifurcation in a 40-year-old man with situs solitus. The left pulmonary artery (LP) has just crossed the left main bronchus (arrow 1). The aortic arch (Ao) is superior and medial to the left pulmonary artery. The coronary sinus (arrow 2) courses to the right of the fat of the posterior atrioventricular ring, beneath the left atrium (LA).

Figure 33-43. Right anterior oblique sagittal spin-echo image obtained from a 38-year-old man. The aortic arch (Ao) and the left pulmonary artery (LP), just after it crosses the left bronchus (arrow 1), are seen. The left upper lobe pulmonary vein (arrow 2) enters the left atrium (LA) just superior and posterior to the orifice of the left atrial appendage (arrow 3). The left atrium and the left ventricle (LV) are separated by the mitral valve (arrows 4).

phologic left bronchus is the bronchus that takes a long course from the tracheal bifurcation before giving origin to the left upper lobe bronchus; the right bronchus is the bronchus that travels for a short distance prior to the origin of the right upper lobe bronchus. The left pulmonary artery courses over the left bronchus; the right pulmonary artery runs anterior and slightly inferior to the right bronchus. Atrial situs inversus is the mirror-image analogue of situs solitus (Fig. 33-45). The morphologic right atrium lies on the left, and the morphologic left atrium is on the right.

Situs ambiguous may be indicated by the presence of symmetrical left-sided and right-sided bronchi. Two left-sided bronchi indicate left isomerism (Fig. 33-46); two right-sided bronchi indicate right isomerism. In atrial situs solitus, the upper abdominal aorta lies to the left of midline and the inferior vena cava to the right; in atrial situs inversus, the abdominal aorta lies to the right. In situs ambiguous, both the aorta and inferior vena cava lie on one side of the midline; on the left side in left isomerism, and on the right in right isomerism. Furthermore, the inferior vena cava in patients with situs ambiguous lies anterior to the aorta.

Ventricular Morphology

The right and left ventricles may be confidently differentiated by their shape, trabecular appearance, and relationship between atrioventricular and semilunar valves. The endocardial surface of the morphologic left ventricle appears smoother than that of the morphologic right ventricle.

Figure 33-45. Coronal spin-echo acquisition through the tracheal (T) bifurcation in a 6-year-old boy with coarctation of the aorta in complete situs inversus. The left-sided (morphologic right) pulmonary artery (RP) runs over the top of the right-sided bronchus (arrow 1) and lies inferior and lateral to the aortic arch (arrow 2). The aortic arch is diminished in caliber, and the right subclavian artery (RS) is dilated.

The muscular trabeculations of the morphologic right ventricle are thicker and straighter than those of the relatively smooth-appearing left ventricle. These trabeculations are most apparent along the right ventricular side of the interventricular septum. The left ventricle has large papillary muscles that only originate from the free wall. Tricuspid valve papillary muscles originate from both the interventricular septum as well as the free wall of the right ventricle. These are visualized as soft tissue within the right ventricular cavity on spin-echo examination and as filling defects, which increase in size in systolic images, using gradient-echo acquisition. The most reliable means of differentiating the right ventricle from the left ventricle is by demonstration of the right ventricular infundibulum. This circumferential band of myocardium separates the tricuspid valve from the semilunar valve. MR examination is useful for demonstrating the right ventricular infundibulum (Fig. 33-47). The left ventricle has no infundibulum. There is fibrous continuity between the mitral and semilunar valves (Fig. 33-48).

Cardiac Looping

During the third week after fertilization, the ventral cardiac tube loops toward the embryonic right (D [dexter]-looping). As a result of this, the inflow to the ventricle derived from the bulbus cordis subsequently lies to the right of the inflow to the ventricle formed from the true ventricle. By the sixth week after fertilization, the D-looped

Figure 33-46. Coronal spin-echo acquisition obtained through the tracheal (T) bifurcation and left atrium (LA) from a 76-year-old woman with breast carcinoma. The left-sided bronchus (LB) and the right-sided bronchus (RB) appear symmetrical. The left-sided pulmonary artery (LP) runs over the left bronchus, and the right-sided pulmonary artery (arrow 1) runs over the right bronchus. Note that the inferior vena cava is not shown passing through the liver; a dilated azygos vein (arrow 2) indicates interruption of the IVC azygos continuation. Incidentally, note the dilated left subclavian artery (LS) originating from the distal aortic arch (Ao); the patient also had an unsuspected mild aortic coarctation. AoD, descending aorta.

heart swings around an external axis to come to lie in the left chest, retaining the right-to-left relationship between right and left ventricular inflows. If the heart loops to the left (L [levo]-looping), the inflow to the morphologic right ventricle comes to lie to the left of that of the morphologic left ventricle. Thus, the direction of looping can be ascertained by analysis of the relationships of the inflows of the ventricular chambers.

Atrioventricular and Ventriculoarterial Connection

Atrioventricular concordance exists when blood flows from the morphologic right atrium to the morphologic right ventricle and from the morphologic left atrium to the morphologic left ventricle; this is the result of D-looping of the ventricles (Fig. 33-49). Atrioventricular concordance may exist in either situs solitus (right atrium to the right) or situs inversus (right atrium to the left). An L-looped heart exhibits atrioventricular discordance; right atrial blood flows to the morphologic left ventricle and left atrial

Figure 33-47. Right anterior oblique sagittal spin-echo acquisition through the anterior aortic sinus of Valsalva (a) in a 24-year-old woman with an atrial septal defect. The main pulmonary artery (PA) is dilated, as compared with the ascending aorta (Ao). The tricuspid valve (arrow 1) separating the right atrium (RA) from right ventricle (RV) itself is separated from the pulmonary artery by the right ventricular infundibulum (arrow 2).

Figure 33-48. Oblique sagittal spin-echo acquisition through the aortic valve (arrow 1) in a 9-year-old boy with a bicuspid aortic valve. The valve is thickened, and its caliber is diminished. The anterior mitral leaflet (short arrows) attaches to the aortic valve. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 33-49. Axial early systolic gradient-echo image obtained from a 15-year-old boy with coarctation of the aorta. The line AB is drawn through the center of the heart, just to the left of the posterior right aortic sinus of Valsalva (pr). In a D-loop, the inflow (arrow 1) to the right ventricle (RV) lies to the right of the inflow (arrow 2) to the left ventricle (LV). LA, left atrium; RA, right atrium.

blood flows to the morphologic right ventricle (Fig. 33-50). Note that D-looping in atrial situs inversus results in L-loop atrioventricular relations and that L-looping in situs inversus results in D-loop relations.

Ventriculoarterial concordance exists when the morphologic right ventricle supports the pulmonary valve and pulmonary artery (see Fig. 33-47) and when the morphologic left ventricle supports the aortic valve and aorta (see Fig. 33-48). Thus, the normal great artery relationship is for the aorta to be to the right with respect to the pulmonary artery (see Fig. 33-3). Ventriculoarterial discordance therefore exists when the right ventricle supports the aorta or the left ventricle supports the pulmonary artery. Generally, ventriculoarterial discordance occurs in two important lesions: (1) D-transposition of the great arteries (D-TGA) and (2) congenitally corrected TGA (CC-TGA or L-TGA). In the former, there is ventriculoarterial discordance in the presence of atrioventricular concordance (Fig. 33-51). In CC-TGA, the association of both atrioventricular and ventriculoarterial discordance results in a double-switched circulation (Fig. 33-52). MR examination may be useful in diagnosing CC-TGA either by explicit demonstration of discordant connections or simply by demonstration of the left-sided upper heart border forming the aorta and the medially located main pulmonary artery segment.^{117, 218}

Bicuspid Aortic Valve

Congenital bicuspid aortic valve is the most frequent malformation of the aortic valve, occurring in 0.9% to 2% of all individuals in autopsy series.²⁴⁸ Although the valve may be stenotic with commissural fusion at birth, it is

Figure 33–50. MR image obtained from a 7-month-old boy with situs solitus, corrected transposition of the great arteries, ventricular septal defect (VSD), and pulmonary atresia.

A, Axial section through the VSD (*arrow 1*). The line CD is drawn through the center of the heart. In an L-loop, the inflow to the right ventricle (RV) is to the left of the inflow to the left ventricle (LV). The identity of the morphologic left atrium is determined by the characteristic long left atrial appendage (*arrow 2*); the right atrial appendage (*arrow 5*) is short and broad-based. Notice the large collateral vessel (*arrow 4*) arising from the descending aorta. LA, left atrium; RA, right atrium.

B, Coronal spin-echo section through the ventricles. The right-sided ventricle gives papillary muscles only from the free wall; this is the morphologic left ventricle. The left-sided ventricle gives papillary muscles from the interventricular septum (*arrows*) as well as the free wall; this is the morphologic right ventricle.

Figure 33–51. D-Transposition of the great arteries in a 4-year-old child. *A*, Sagittal section through the aortic valve. The anterior aorta (Ao) and aortic valve (*arrow 1*) are separated from the tricuspid valve (*arrow 2*) and right atrium (RA) by the circumferential muscular right ventricular (RV) infundibulum (In). *B*, Coronal section through the aortic valve (*arrow 2*). The aorta (Ao) is toward the right. The tricuspid valve (*arrow 1*) that connects the right atrium (RA) and right ventricle (RV) is separated from the aortic valve.

Figure 33-52. Coronal spin-echo acquisition from a 2-year-old boy with double-inlet left ventricle, congenitally corrected transposition of the great arteries, and tricuspid atresia. The thymus (T) has not yet regressed. The morphologic right atrium (RA) is connected to a ventricular chamber whose atrioventricular valve (arrow 1) is continuous with the pulmonary valve (arrow 2); this is the morphologic left ventricle (LV) (atrioventricular discordan- ce). The hypoplastic right ventricle (RV) is filled across a ventricular septal defect (arrow 3) (also known as a *bulboventricular foramen*) and supports a left-sided aorta (Ao) (ventriculoar- terial discordan- ce). PA, pulmonary artery.

more commonly not responsible for severe stenosis in childhood. However, these valves tend to present later in life, usually by late adolescence. Fibrosis, increasing rigid- ity and calcification of the leaflets, and subsequent nar- rowing of the aortic orifice³⁵ develop as a result of turbu- lence associated with the abnormal valvular architecture. Stenotic changes resemble those found in cases of degener- ative calcific stenosis of a tricuspid aortic valve, but these changes occur several decades earlier in the congenitally malformed valve. About one third of patients born with congenital bicuspid aortic valve remain free of any hemo- dynamically significant problem. Valvular stenosis devel- ops in about one third of patients. An additional one third of patients develop aortic regurgitation⁸⁷ on the basis of organic structural abnormality or after a bout of acute bacterial endocarditis.

The aortic annulus in these patients may be normal, but in more severe cases it is decreased in caliber. The three aortic sinuses of Valsalva may be maldistributed by the unseparated valvular commissures; the valve leaflets them- selves may be thickened (Fig. 33-53). Calcium is transpar- ent on MR examination; valvular calcification may have the appearance of thickened loci of signal void relating to the valve annulus or where one expects to find valve leaflets. Aortic valve doming may be demonstrated in off- coronal or sagittal section (Fig. 33-54). Often, dilata- tion of the ascending aorta and left ventricle is identified in cases of valves with mixed stenosis and regurgitation. In both instances, there is left ventricular hypertrophy; in mixed regurgitant bicuspid aortic valves, left ventricular hypertrophy is less apparent because the left ventricle is dilated as well. Gradient-echo imaging of the abnormal valve produces typical systolic signal-void jets of aortic

Figure 33-53. MR images obtained from two adult patients with congenital bicuspid aortic valve disease. **A**, Axial spin-echo acquisition from a 23-year-old man. Notice the asymmetry of the two aortic sinuses of Valsalva (S1 and S2). The left ventricular (LV) myocardium is thickened; note the severe hypertrophy of the papillary muscle (arrow). RV, right ventricle. **B**, Systolic short-axis gradient-echo acquisition from a 27-year-old man. There is mild dilatation of the aortic root. The limited valve orifice appears as increased signal intensity sandwiched between the two aortic valve leaflets (arrows). LA, left atrium; RA, right atrium; RV, right ventricle.

Figure 33-54. Midsystolic oblique coronal spin-echo acquisition from a 19-year-old man with congenital bicuspid aortic stenosis. The center of the image has been image-processed to bring out the appearance of the aortic leaflets (*arrows*). Notice that the leaflets are thickened and leave a limited valvular orifice. The left ventricular (LV) myocardium is thickened, and there is mild dilatation of the ascending aorta (Ao).

Figure 33-55. Systolic oblique coronal gradient-echo acquisition through the main pulmonary artery (PA) from a 24-year-old woman with bicuspid aortic valve stenosis and an acute aortic dissection. The left ventricular (LV) myocardium is hypertrophied. A signal void jet (*arrow 1*) originates from the signal void of the calcified aortic valve (*arrow 2*) and ricochets off the intimal flap, which separates the true aortic lumen from the false lumen (F). RA, right atrium.

Figure 33-56. MR image obtained from a 30-year-old man with bicuspid aortic valve and aortic regurgitation. A, Diastolic oblique axial acquisition through the aortic valve (Ao) at the entry of the superior vena cava (SV) into the right atrium and the right atrial appendage (RAA). The signal void jet of aortic regurgitation (*arrow*) passes along the anterior mitral leaflet and strikes the posterior left ventricular (LV) wall. LA, left atrium; RV, right ventricle. B, In this diastolic short-axis image, the signal void jet is seen in cross-section (*arrows*). RV, right ventricle.

stenosis (Fig. 33-55) and diastolic jets of regurgitation (Fig. 33-56). Correlation between length of signal loss into the aorta and gradient across the valve¹⁹⁹ has been demonstrated in adult patients with aortic stenosis. Direct quantitation of valvular gradients may be obtained by use of phase-velocity mapping.^{150, 151} By acquiring images with a sufficiently short echo time (<5 msec), signal loss from all but the most turbulent regions of poststenotic blood flow is eliminated. Signal intensity measurements across the face of a poststenotic jet are proportional to the flow-velocity profile across the valve. Thus, application of a modified Bernoulli equation to flow-velocity measurements provides a noninvasive estimate of valve pressure gradient.

Coarctation of the Aorta

The most common symptomatic congenital lesion of the aortic arch studied by magnetic resonance is coarctation of

Figure 33-57. Oblique sagittal spin-echo acquisition through the posterior right aortic sinus of Valsalva (pr) from an 11-year-old boy with a 35-mm gradient between upper and lower extremities. The left atrium (LA) and the right atrium (RA) are labeled. Notice the long and undulating course of the ascending aorta and aortic arch. The dilated innominate artery (IA) origin immediately behind the innominate vein (I), the origins of the left common carotid artery (arrow 1) and the left subclavian artery (arrow 2) are seen. The left subclavian artery appears to run nearly parallel to the distal aortic arch immediately above the coarctation (arrow 3) itself.

Figure 33-58. MR image obtained from two children with coarctation of the aorta. *A*, Coronal spin-echo acquisition from a 6-month-old girl with a 50-mm aortic gradient. The proximal descending aorta (parallel long arrows) distal to the origin of the dilated left subclavian artery (arrow 1) tapers to the point of maximal stenosis. Aortic collateral vessels (arrowheads) are seen entering the aorta distal to the coarctation. The azygos vein (Az) is labeled. *B*, The patient is a 4-year-old boy with a 60-mm gradient. Left anterior oblique sagittal spin-echo acquisition through the posterior right (pr) aortic sinus of Valsalva. The left (LA) and right (RA) atria are marked. The ascending aorta (Ao) is mildly dilated, and there is hypoplasia of the arch extending from the origin of the innominate artery (IA), beyond the origin of the left subclavian artery (LS) to the actual coarctation itself (arrow). Beyond the coarctation, there is mild poststenotic dilatation. CS, coronary sinus.

the aorta.^{146, 306} Coarctation of the aorta is a congenital maldevelopment of the aorta (Fig. 33–57), which presents with hypoplasia of the distal aortic arch and focal narrowing of the proximal descending aorta, almost invariably at the junction of the ductus arteriosus and aorta.

Collateral circulation to the postcoarctation segment usually originates from branches of the proximal subclavian arteries (the internal mammary arteries and thyrocervical trunk). Blood flow is around the shoulder or anterior chest wall and retrograde through the intercostal arteries to the postcoarctation segment of the proximal descending aorta. Occasionally, coarctation of the aorta may be associated with an aberrant subclavian artery. In such circumstances, the aberrant artery is downstream from the coarctation (at low pressure with respect to the ascending aorta) and thus unable to provide collateral flow to the postcoarctation aorta. Plain film examination in these cases may reveal unilateral rib notching.

MR examination of patients with coarctation of the aorta is directed toward demonstration of the location and length of the coarctation segment (Fig. 33–58), the status of the aortic isthmus, and the degree of arterial collateralization present.^{28, 146, 279, 306} Furthermore, the relationship of the coarctation to the origins of the left and right subclavian arteries (especially in cases with an aberrant subclavian artery) must be demonstrated. These changes are usually best appreciated in oblique sagittal or coronal sections, parallel to the axis of the ascending and descending aortas. However, in smaller children or older adults, the small caliber of the aorta or aortic tortuosity may necessitate acquisition in additional oblique sections. The origin of the left subclavian artery in many of these patients appears to be “pulled” inferiorly from the distal aortic arch toward the hourglass deformity of the coarctation itself, the so-called capture of the left subclavian artery (see Fig. 33–57). In oblique sagittal sections from the posterior chest, dilated intercostal arteries may be identified traveling along the underside of the posterior upper ribs (Fig. 33–59). The internal mammary arteries run along the inner aspect of the anterior chest wall, on either side of the lateral border of the sternum, and are best identified in axial or coronal section as dilated signal voids (Fig. 33–60). MR examination is a useful means of following the results of balloon dilatation and surgical repair of coarctation.^{236, 286} Serial examination allows close follow-up and assessment of residual stenosis and early demonstration of aneurysmal dilatation.

Patent Ductus Arteriosus

The ductus arteriosus is the persistent distal left sixth aortic arch. It extends from the underside of the aortic arch just distal to the origin of the left subclavian artery to the left pulmonary artery near its origin. Usually the ductus is left sided, but, in cases of right aortic arch, it may be right sided. Bilateral patent ductus arteriosus is rarely found. This abnormality has a variable morphology. The most common shape of a patent ductus arteriosus is long and cylindrical (Fig. 33–61). An hourglass-like narrowing may be found in its midportion. Frequently, the patent duct has a funnel shape. In this variety there is a broad base on the

Figure 33–59. Left anterior oblique sagittal spin-echo acquisition through the interatrial septum from a 14-year-old boy with a 50-mm gradient across the coarctation. The left atrium (LA) and right atrium (RA) and the right pulmonary artery (RP) are labeled. Intercostal collateral vessels appear as serpiginous signal voids along the undersides of the ribs (arrows).

aortic side and a narrow attachment to the pulmonary artery. Aneurysmal ducti are less common but may appear saccular or spindle shaped. The variable length and orientation of the duct between the aorta and pulmonary artery make its demonstration often difficult. In the coronal section, communication between the underside of the distal aortic arch or proximal aorta with the superior aspect of the left pulmonary artery may be easily demonstrated. Right anterior oblique sagittal section through the arch or proximal descending aorta may demonstrate ductal communication. MR examination for patent ductus arteriosus in infants may be limited by the size of the ductus and spatial resolution of the scanner (Fig. 33–62). There are no data concerning the sensitivity and specificity of MR examination in the diagnosis of patent ductus arteriosus.

Pulmonary Arteries

Echocardiographic examination of the pulmonary arteries may be limited.^{125, 208} MRI complements echocardiographic examination for the assessment of the size, patency, confluence, and character of the extraparenchymal pulmonary arteries (Fig. 33–63).^{44, 73, 103} Pulmonary arterial anomalies, including pulmonary artery sling and origin of the

Figure 33-60. Coronal spin-echo acquisition through the posterior aspect of the sternum in a 16-year-old boy with coarctation of the aorta. Both the left and right (arrows) internal mammary arteries are dilated and serpiginous.

Figure 33-62. Off-axial spin-echo image obtained from a 5-week-old girl with heart failure. The thymus (T) has not regressed. The main pulmonary artery (PA) is dilated and greater in caliber than the ascending aorta (Ao). The right pulmonary artery (arrow 2) lies behind the superior vena cava (SV) and in front of the right bronchus (arrow 3). The patent ductus is the signal void communication (arrow 1) between the top of the pulmonary artery and the descending aorta (AoD).

Figure 33-61. Coronal spin-echo acquisition through the trachea (T) and tracheal bifurcation and posterior left atrium (LA) from a 24-year-old woman with pulmonary hypertension. The tubular communication (arrow 1) between the underside of the distal aortic arch (Ao) and the top of the left pulmonary artery (arrow 2) is the patent ductus.

Figure 33-63. Coronal spin-echo acquisition through the trachea (T) and the tracheal bifurcation from a 16-month-old boy with tetralogy of Fallot with pulmonary atresia and right branch pulmonary artery stenosis. The aortic arch (Ao) is right-sided. There is focal narrowing of the transverse right pulmonary artery (RP) (arrows) as the artery crosses over the left atrium (LA).

pulmonary artery from the ductus arteriosus, may be characterized directly. Increased pulmonary blood flow, increased pulmonary artery pressure, and poststenotic dilatation of the pulmonary artery can be differentiated based on the character of flow within the dilated pulmonary artery segments. Dilated central pulmonary artery segments without increased signal indicates increased flow (see Figs. 33–36A, 33–45, and 33–62); if increased signal is present, pulmonary artery pressure is elevated. Dilatation of the main pulmonary artery, with or without associated left or right pulmonary arterial enlargement, may be seen in patients with valvular pulmonic stenosis. Aneurysmal dilatation of the pulmonary arterial tree may be found in patients with chronic, mild valvular pulmonic stenosis or pulmonary insufficiency. In patients with pulmonary hypertension and long-standing left-to-right shunts, the pulmonary arterial wall is thickened and increased in signal intensity. The central pulmonary arteries in cases of right ventricular outflow obstruction (including pulmonary atresia or tetralogy of Fallot with pulmonary atresia) may be diminutive or, if atretic, not identifiable. Focal branch stenosis proximal to the pulmonary hila may be identified directly. The main and central pulmonary arteries in cases of supra-valvular pulmonic stenosis (as an isolated lesion, or in association with Williams or Noonan's syndromes), reveal diffuse or focal wall thickening (Fig. 33–64). Similarly, pulmonary arterial banding results in focal pulmonary artery narrowing.

Congenital Pulmonary Stenosis

The most common form of congenital pulmonic stenosis is valvular. So-called supra-valvular pulmonic stenosis is actually pulmonary arteritis with segmental stenosis and is commonly a component of Noonan's syndrome, Williams

syndrome, and congenital rubella syndrome. Subvalvular stenosis is the result of local right ventricular infundibular hypertrophy; the valve is usually normal in these individuals.

In patients with noncritical pulmonic stenosis, the pulmonary valve leaflets thicken and fibrose with age, but calcification is rarely found. Right ventricular hypertrophy reflects the severity and duration of the valvular obstruction. Right-sided heart failure is uncommon in infancy and before the 5th decade. Prolonged right ventricular hypertension distorts chamber geometry, causing right ventricular papillary muscle dysfunction and tricuspid regurgitation. Some patients with moderate stenosis progress to more severe obstruction owing to late fibrosis and deformity of the valve leaflets, or superimposed infundibular hypertrophy. Survival into the 7th decade in patients with valvular pulmonary stenosis has been reported.^{104, 113}

MR examination in these patients is directed toward differentiating valvular disease from diseases resulting in dilatation of the main pulmonary artery. In patients with valvular pulmonic stenosis, the main and either left or both left and right proximal pulmonary arteries are dilated. Pulmonary blood flow in these patients is normal, so a signal void is expected when examined using spin-echo technique. Gradient-echo acquisition through the right ventricular outflow and proximal main pulmonary artery shows a systolic jet of signal void owing to turbulence extending into the main or left pulmonary artery. Right ventricular hypertrophy is the rule in these individuals but, depending on the severity of the myocardial hypertrophy, the amount of tricuspid regurgitation is variable. Therefore, right ventricular dilatation is unusual, and clockwise cardiac rotation is not usually seen (Fig. 33–65).

Intracardiac Shunts

MR examination is useful for the diagnosis of intracardiac shunt by explicit demonstration of the defect. Alternatively, it may be used to define the constellation of specific chamber dilatation and hypertrophy that may be used to characterize a particular lesion, confirming questionable cases and excluding false-positive cases.

Atrial Septal Defect

Atrial septal defects (ASDs) may be classified on the basis of the location of the defect. *Primum defects*, whether or not they are associated with other atrioventricular septal defects, are medially located, immediately superior to the atrioventricular valves (Fig. 33–66). *Secundum defects* are centrally located in the septum and are usually large. These may be differentiated from a patent foramen ovale by their size (Fig. 33–67). *Sinus venosus defects* are laterally located, appearing as defects between the posteroinferior border of the inferior vena cava and the left atrium, immediately inferior and posterior to the entry of the right upper lobe pulmonary vein (Fig. 33–68).

The interatrial septum is best visualized in axial and left anterior oblique sagittal or short-axis section (Fig. 33–69; see also Fig. 33–67A). It is often infiltrated with fat, in-

Figure 33–64. Axial spin-echo acquisition through the right ventricular outflow tract (RVO) and left atrial appendage (arrow 1) from a 37-year-old man with Williams syndrome. Note the infundibular right ventricular hypertrophy (arrowheads). Turbulence in the right pulmonary artery (arrow 2) extends from beyond stenosis at its origin. Ao, aorta; LP, left pulmonary artery.

Figure 33-65. MR image obtained from a 74-year-old woman with congenital valvular pulmonic stenosis. *A*, Systolic sagittal gradient-echo acquisition obtained through the pulmonary valve. Two signal voids on the cusps of the pulmonary valve (arrows 1 and 2) represent calcific leaflet deposits. A fan-shaped jet of pulmonic stenosis (arrowheads) into the dilated main pulmonary artery (PA) can be seen. In this anatomic section, the anterior mitral leaflet (arrow 3) can be seen separating the left atrium (LA) from left ventricle (LV). RV, right ventricle. *B*, Systolic oblique axial section through the stenotic pulmonary valve (arrows). The valve orifice has been outlined in black. One can see how valve area can be directly quantitated by this technique. Ao, aorta; AoD, descending aorta; SV, superior vena cava.

Figure 33-66. MR image obtained from two children with an atrioventricular septal defect (ASD) and a primum ASD. *A*, Axial spin-echo acquisition from a 21-month-old girl. Both the right atrial appendage (RAA) and the left atrium (LA) are dilated. There is a break in the medial aspect of the interatrial septum (arrow 1), indicating a primum ASD. In addition, there is a break in the posterior interventricular septum (arrow 2) and a solitary bridging atrioventricular valve (arrow 3). The right ventricular (RV) myocardium is severely hypertrophied. Incidentally, in this child with duplication of the superior vena cava, the left vena cava drains to the dilated coronary sinus (CS).

B, Systolic axial gradient-echo acquisition from a 15-month-old boy with ASD. Note the severe hypertrophy of the right ventricular (RV) and the septal myocardium. The signal void jet (arrow 1) extending from just beneath the posterior right aortic sinus of Valsalva into the right atrium (RA) is the shunt through the atrioventricular septal defect. In addition, the signal void jet (arrow 2) extending from the mitral valve into the left atrium represents mitral regurgitation through a cleft mitral leaflet. LV, left ventricle.

Figure 33–67. MR image obtained from two adult patients with secundum atrial septal defects. *A*, Axial spin-echo acquisition from an asymptomatic 57-year-old woman. The heart has rotated in a clockwise manner into the left chest; the right atrium (RA), the right ventricle (RV), and the left lower-lobe pulmonary vein (*single-headed arrow*) are dilated. The interventricular septum is flat. However, the left atrium (LA) and left ventricle (LV) are normal. The atrial septal defect (*double-headed arrow*) is in the center in the interatrial septum. *B*, Short-axis section from a 43-year-old asymptomatic woman. The dilated right ventricle (RV) has extended below the normal-appearing left ventricle (LV). Despite the RV dilatation, the right ventricular free wall myocardium (*arrowheads*) is not hypertrophied, but the interventricular septum (*short arrows*) is flattened.

Figure 33–68. MR image obtained from a 28-year-old woman with sinus venosus atrial septal defect. *A*, Right parasagittal gradient-echo acquisition through the entrance of the superior vena cava (SV) into the right atrium (RA). The defect results in continuity among the lower SV, the left atrium (LA), and the right atrium. RAA, right atrial appendage; RP, right pulmonary artery. *B*, Axial spin-echo acquisition through the right atrium (RA) and right ventricle (RV). The right atrium, right ventricle, and coronary sinus (CS) are each dilated, and the heart is rotated into the left chest. The interventricular septum is flat, and RV myocardial trabeculae in this patient are more prominent than in the patient in Figure 33–67*B*. Note the high-signal-intensity crista terminalis (*arrow*) along the lateral aspect of the RA wall. LV, left ventricle.

Figure 33-69. Diastolic short-axis acquisition through the interatrial septum in a 30-year-old woman with a secundum atrial septal defect. The interatrial septum is bowed toward the right atrium (RA). The signal void jet of the shunt (arrows) extends from the septum into the dilated RA. The left atrium (LA) is smaller than the RA, and the right pulmonary artery (RP) is dilated.

creasing its conspicuity against the signal void of the two atria, and normally bows toward the right atrium. The septum is thinner in the region of the foramen ovale. Care must be taken to avoid making the misdiagnosis of an atrial septal defect based solely on the isolated observation of a break in the septal contour. The diagnosis of a shunt is ensured if the associated morphologic and anatomic changes resulting from the altered flow of blood are identified. In particular, in an atrial septal defect, blood shunts across the atrial septum to volume-load the right atrium and ventricle and pulmonary arteries. Volume loading the right heart results in clockwise (looking from below) cardiac rotation. The plane of the interventricular septum is nearly parallel to the coronal plane. In patients with atrial septal defect, the left atrium decompresses during diastole and is therefore not enlarged. Right ventricular myocardium in simple atrial septal defect is not hypertrophied. The direction of the shunt (left-to-right or right-to-left) can be assessed using gradient-echo technique. Of course, such characterization is dependent on finding the anatomic level of the shunt itself and imaging the defect in a plane to the flow of blood. Administration of intravenous Gd-DTPA may help characterize smaller or less apparent shunts.¹⁷⁵ Atrial-level shunts may be quantitated by means of analysis of velocity-encoded cine MR images.³⁶ Imaging in the axial plane, MR has an overall 97% sensitivity and 90% specificity for the detection of atrial septal defects.⁷²

Ventricular Septal Defect

MRI is a valuable means of diagnosing the presence and size of ventricular septal defects.^{74, 135, 340} Large subaortic ventricular septal defects are readily demonstrated on axial spin-echo images as signal voids to the left of the atrioventricular rings and to the right of the crest of the muscular interventricular septum (Fig. 33-70). Separation of the actual defect from the caudal extension of an aortic sinus of Valsalva is best appreciated by obtaining images in oblique sagittal section through the base of the heart. Smaller, and more distal, defects are more difficult to demonstrate directly using spin-echo technique and often necessitate construction of compound angulated sections. GRE cine acquisition portrays the turbulent blood flowing across the defect as a signal-void jet within the cavity of the right ventricle (Fig. 33-71). Membranous ventricular septal defects are identified by the absence of signal in the posterior, superior-most aspect of the interventricular septum, immediately below the aortic valve, and adjacent to the septal leaflet of the tricuspid valve. Supracristal defects may be identified in right anterior oblique sagittal section, or in axial section, immediately below the semilunar valves. Anterior extension into the muscular septum can be identified in axial or right anterior oblique sagittal sections through the interventricular septum. Muscular ventricular septal defects are more difficult to identify directly by spin-echo technique but may be identified by detection of the signal-void jet of the shunted blood using gradient-echo methods (Fig. 33-72). Careful evaluation of cine imagery allows differentiation among left-to-right, right-to-left, and bidirectional shunts.

Other Shunts

Atrioventricular septal defects (endocardial cushion defects) may involve the anterior mitral and septal tricuspid valve leaflets, the membranous interventricular septum, as

Figure 33-70. Oblique axial spin-echo acquisition through the posterior right aortic sinus of Valsalva (pr). The large membranous ventricular septal defect (arrow 1) communicates between the dilated and hypertrophied right ventricle (RV) and the left (LV) ventricle. The visualized right pulmonary artery (RP) lies anterior to the right bronchus (arrow 2). Notice how the unsupported aortic sinus overrides the septum toward the right ventricle. LA, left atrium; RAA, right atrial appendage; SV, superior vena cava.

Figure 33-71. Systolic horizontal long-axis section through the posterior interventricular septum in a 50-year-old man with a pinhole ventricular septal defect. At the apex (arrows) of a ventricular septal aneurysm that extends between the crest of the muscular interventricular septum (**) and the annulus of the aortic valve is the fan-shaped signal void shunt jet into the right ventricle (RV). Ao, aorta; LA, left atrium; LV, left ventricle.

well as the atrioventricular septum and primum portion of the interatrial septum (see Fig. 33-66). Precise classification based on the morphology of the common atrioventricular valve is difficult with MR, but such defects may be characterized by the extent of endocardial cushion abnormality.^{135, 219} MRI is useful in determining the size of the ventricular component of the defect as well as the presence of ventricular hypoplasia. Gradient-echo acquisition may be helpful in confirming primum atrial septal defects and demonstrating atrioventricular shunting.

Anomalous pulmonary veins may return to systemic veins above the level of the heart, including the innominate and subclavian veins, or superior vena cava. Veins may drain directly to the right atrium or coronary sinus or below the level of the heart, to the inferior vena cava or portal vein. Axial spin-echo acquisition almost always demonstrates the four pulmonary veins. In a series of 56 patients with various types of congenital heart disease but normal pulmonary venous connection, axial spin-echo MRI showed the sites of connection of all four pulmonary veins in 88% of cases; in a parallel series of 22 patients with partial or total anomalous pulmonary venous return, pulmonary venous anomalies were identified in 95% of cases¹⁸⁵ (Fig. 33-73).

Anomalies of individual pulmonary veins are rare but may be identified using MRI. Pulmonary vein stenosis may be identified by the increased intraluminal signal intensity of obstructed venous inflow to the heart.²⁵⁴ Pulmonary venous varix may be identified as a dilated tubular structure confluent with the left atrium.³²⁶

Tetralogy of Fallot

The underlying malformation in patients with tetralogy of Fallot is the malalignment of the ventricular septal

Figure 33-72. MR images obtained from a 5-year-old boy with a muscular ventricular septal defect. *A*, Oblique sagittal spin-echo acquisition through the aortic root (Ao). The defect (arrow) is well away from the membranous interventricular septum and the aortic annulus. LA, left atrium; RAA, right atrial appendage; RP, right pulmonary artery; RV, right ventricle; T, thymus. *B*, Systolic axial gradient-reversal acquisition through the defect shows the fan-shaped signal void jet (arrows) extending from the dilated left ventricle (LV), through the septum, and into the right ventricle (RV). LA, left atrium.

Figure 33-73. Axial spin-echo acquisition from a 23-year-old woman with a sinus venosus atrial septal defect, partial anomalous pulmonary venous return, and bilateral superior venae cavae. The main pulmonary artery (PA) and the right pulmonary artery (RP) are dilated, as is the left lower lobe pulmonary vein (arrow 1). The lateral aspect of the right-sided superior vena cava (SV) is incomplete at the site of entry of the anomalous right upper lobe pulmonary vein (arrow 2). Note the signal void of the left-sided superior vena cava (ls) as it enters the lateral horn of the coronary sinus. Ao, aorta; LA, left atrium.

defect. The degree to which the crista supraventricularis is malaligned determines the severity of right ventricular outflow obstruction as well as the size of the aortic root and the incidence of aortic regurgitation.¹⁷⁹ Aortic regurgitation is found in more than three fourths of adult patients with tetralogy of Fallot with pulmonary atresia.⁴⁵ This volume loads both left and right ventricles but has a more significant effect on the already pressure-loaded right ventricle.

Evaluation of a patient with tetralogy of Fallot requires a series of acquisitions in different planes to characterize the severity of right ventricular outflow obstruction, the ventricular septal defect, and pulmonary morphology. Furthermore, one must assess the status of systemic-to-pulmonary artery collateral vessels and palliative surgical shunts, if present. The typically large perimembranous ventricular septal defect is usually well demonstrated in axial¹⁹⁸ or sagittal section (Fig. 33-74A). Aortic caliber and position of the aortic valve with respect to the interventricular septum are explicitly demonstrated in sagittal section (see Fig. 33-33). Slightly cephalad to the ventricular septal defect, the narrowed right ventricular outflow tract and hypertrophied infundibulum may be evaluated (Fig. 33-74B). Off-coronal section aids in demonstrating confluence of the pulmonary arteries as well as focal pulmonary artery stenosis (see Fig. 33-63). Addition of coronal imaging is helpful in demonstrating the presence and extent of systemic to pulmonary artery collaterals. Use of either spin-echo or gradient-echo images allows measurement of the size of the main pulmonary artery and each major branch, as well as the adequacy of the central pulmonary confluence. The most commonly used surgical shunt in these patients is a modified Blalock-Taussig shunt. MRI is effective in demonstrating the potency and defining the severity of stenosis within the shunt. Velocity-encoded cine MRI

Figure 33-74. MR images obtained from a 53-year-old woman with tetralogy of Fallot. She had received palliative treatment 45 years earlier with a Blalock-Taussig shunt. **A**, Left anterior oblique sagittal spin-echo acquisition through the aortic root shows how the large subaortic ventricular septal defect (VSD) (paired arrows) affords communication between the hypertrophied right ventricle (RV) and the mildly dilated left ventricle (LV). The aortic root overrides the VSD. The origin of the right coronary artery (arrow 2) is seen. Arrow 1, left atrial appendage. **B**, Axial spin-echo acquisition obtained through the aortic valve. The anteriorly malaligned crista supraventricularis (arrows) causes posterior impingement on the hypertrophied right ventricular outflow (RVO) and leaves the VSD behind. Notice the right-sided descending aorta (Ao) in this patient with a mirror-image right aortic arch. LA, left atrium; LV, left ventricle; RA, right atrium.

can be used to measure flow and estimate gradients in these structures. Imaging palliative Blalock-Taussig shunts is best performed in plane with the long axis of the grafts, that is, in oblique sagittal or coronal section.

In cases of pulmonary atresia, there is increased fat deposition in the region of the atretic valve ring.¹⁴⁷ The main pulmonary artery may be identified (and even enlarged) if a surgical shunt procedure was performed prior to examination. More commonly, however, the pulmonary arteries are hypoplastic (Fig. 33–75). Determination of pulmonary artery continuity and exclusion of focal pulmonary artery stenosis are goals of MR examination. The right ventricular myocardium in pulmonary atresia with intact septum is markedly hypertrophied, more so than found in tetralogy of Fallot. The right ventricular cavity is small, the actual size being dependent on the size and competence of the tricuspid valve. The aorta in pulmonary atresia with ventricular septal defect as well as in tetralogy of Fallot is dilated. MR examination provides detailed anatomic information concerning the morphology of the right ventricular outflow tract, the size and course of the central pulmonary arteries, and the sources of collateral blood flow to the lungs^{93, 147, 235} in these patients. Systemic-to-pulmonary artery collaterals are usually found posterior to the trachea and main bronchi. MR examination tends to underestimate their number²³⁵ but is useful in demonstrating their origin. The site of connection with the pulmonary arterial tree is often not seen. Patency of palliative shunts may be assumed when no intraluminal signal is identified on spin-echo examination.^{147, 235}

Figure 33–75. Sagittal spin-echo acquisition from a 14-month-old girl with pulmonary atresia and a ventricular septal defect (VSD). The dilated ascending aorta overrides the VSD (arrow 1) between the left ventricle (LV) and the hypertrophied right (RV) ventricle. The transverse right pulmonary artery (arrow 2) is severely hypoplastic.

In patients with tricuspid atresia, the anterior atrioventricular ring is replaced by fat,⁹² and no continuity between the right atrium and right ventricle is found (Fig. 33–76). The right atrium is usually enlarged, and the right ventricle is usually smaller than normal. A large interatrial communication can usually be demonstrated. The shunt itself can be characterized using gradient-echo technique. Axial and sagittal acquisition demonstrates commonly associated lesions, including ventricular septal defect, pulmonary atresia, the relationship between the great arteries, as well as complications of elevated systemic venous pressure, such as mediastinal and pericardial venous collaterals. The results of surgical palliation by the Fontan operation may be demonstrated directly.^{136, 148, 212, 217, 261, 285} In addition, application of velocity mapping techniques allows accurate assessment of conduit obstruction.^{183, 234}

Univentricular Hearts

Univentricular heart is a compromise term, adopted to avoid the controversy concerning naming hearts with rudimentary ventricular chambers and unusual atrioventricular connections.³⁰¹ Generally, a double-inlet ventricle is a ventricle that fills from flow across two atrioventricular valves, or through a single (“common”) atrioventricular valve.³⁰³

When the main chamber is morphologically left ventricular in character, the heart is labeled *double-inlet left ventricle* (the most common type); when the morphology is right ventricular in character, then the heart is named *double-inlet right ventricle*. If the main ventricular chamber cannot be characterized as either left or right ventricular, the chamber is referred to as a *common ventricle* or *ventricular chamber*.

MRI is helpful in the evaluation of patients with univentricular hearts and other complex congenital heart lesions. Direct demonstration of right or left ventricular morphology, the relationship between atrioventricular and semilunar valves, and the origins of papillary muscles all are helpful for characterizing the nature of such a ventricle. In these patients, the axial section provides the greatest amount and most reliable information about systemic and pulmonary venous return and great artery relationships. Axial and off-sagittal section provides image data for determination of atrioventricular and ventriculoarterial connections. The interventricular septum in these patients frequently takes an unusual orientation. This and the common association of atrioventricular valvular atresia often necessitate acquisition of coronal as well as off-sagittal sections.

In patients with double-inlet ventricle, both left and right atrioventricular valves empty into a dominant ventricle (Fig. 33–77). Although a rudimentary opposite chamber is usually present, it may appear only as a slit within the posterior or anterior ventricular myocardium. Isolation of the rudimentary (outflow) chamber from atrial inflow is helpful for full characterization of these lesions. In these cases, communication between dominant ventricle and rudimentary ventricular chamber is via a bulboventricular foramen, generally demonstrated in coronal or even axial section (see Fig. 33–52).

Figure 33-76. MR image obtained from a 4-year-old boy with tricuspid atresia. *A*, Axial spin-echo acquisition through the anterior atrioventricular ring (*short arrows*) shows fatty replacement in the atretic valve ring. The interatrial communication (*long arrow*) between right atrium (RA) and the left atrium (LA) is broad. Note the severe hypertrophy of the left ventricle (LV). *B*, Sagittal spin-echo acquisition through the interventricular septum. The severely hypoplastic right ventricle (*arrows*) is no more than a slit in the septum. LV, left ventricle.

Figure 33-77. MR image obtained from a 2-year-old boy with a double-inlet left ventricle (see Fig. 33-52). Blood drains from the right atrium (RA) through the anterior atrioventricular valve (*arrow 1*) and from the left atrium (LA) through the posterior atrioventricular valve (*arrow 2*) into a dominant left ventricle (LV).

The Gastrointestinal Tract

Hyun Kwon Ha, Jeong Kon Kim

General Considerations

Computed tomography (CT) has been increasingly used for patients thought to have a variety of gastrointestinal (GI) tract diseases. Such advances may result from the ability of CT to assess intraluminal, intramural, and extraluminal pathologic processes as well as the development of high-resolution scanners and technical refinements that provide better quality studies. However, it should be stressed that CT is not superior to conventional barium examinations for evaluating mucosal diseases. Therefore, both CT and barium examinations have complementary roles in the diagnosis of GI tract diseases, although both studies are not always required.

Regardless of their primary causes, most inflammatory, neoplastic, and vascular disorders may be recognized on CT by bowel wall thickening or a mass. As our experience has increased in performing and interpreting CT scans, however, we have found considerable overlap of findings in various GI tract diseases. Therefore, to increase the diagnostic accuracy of CT, it is necessary to further investigate bowel wall involvement patterns, such as the degree, length, symmetry, and contrast enhancement in each disease entity. Moreover, observing changes in the perienteric or pericolic spaces, mesentery, omentum, and peritoneal cavity can narrow the differential diagnosis because this information sometimes provides clues for making a specific diagnosis. In addition, CT is renowned for the common occurrence of false-positive findings because nonopacified or poorly distended bowel may simulate masses, tumors, or infection. Thus, adequate CT examination with optimal opacification of the GI tract in an appropriate amount of contrast agent is essential before we can interpret CT scans.

Optimal Techniques for Abdominal CT

Because bowel wall thickening is the single most important indicator of GI abnormality on CT, adequate CT examination of the GI tract requires bowel discrimination and distention, best achieved by administration of both oral and intravenous (IV) contrast material. IV contrast infusion helps to detect the abnormal bowel if the involved bowel shows abnormal contrast enhancement or a *target sign* or *double-halo sign*. Because the cases in which such findings are demonstrated are limited, however, the role of oral contrast material is stressed more than that of IV contrast material for assessment of GI abnormalities. Optimal opacification of the GI tract with an appropriate amount of

contrast agent is essential so as not to overlook those patients with subtle or minimal bowel changes. Furthermore, nonopacified or poorly distended bowel may simulate masses, tumors, or infection.

For the purpose of optimal opacification, the following aspects should be taken into consideration:

1. Type of oral contrast agent.
2. Total volume of oral contrast agent
3. Timing of contrast agent administration.
4. Intestinal transit time.
5. Positioning of the patient.

Although there are no extensive data to support a clear superiority of any particular contrast agent, most institutions have used basically two kinds of oral contrast material: high density or low density. Diluted, 2% to 3% iodine solutions or barium suspensions, which increase the attenuation of the bowel lumen, are most widely used as high-density agents (Fig. 34-1). In contrast, air-density and fat-density contrast agents, which decrease the attenuation of the lumen, can also be used as negative-density agents. Among various agents, 1.5% to 2% barium suspension is the agent that most radiologists prefer.

Barium suspension offers several advantages over water-soluble iodine agents:

1. Barium is relatively palatable.
2. Barium is stable in the pH of the stomach.

Figure 34-1. Diluted barium solution favorably opacifies the lumen of the gastrointestinal tract.

3. There is no cathartic action.
4. Barium is not absorbed by the GI tract.
5. Barium is relatively safe if aspirated, but it should not be used for the patients who are suspected of having peritoneal spillage.

Diluted iodine solutions are water-soluble agents. Therefore, they may be indicated specifically for:

1. Trauma or suspected GI perforation.
2. Use as a bowel marker when percutaneous CT-guided interventional procedures are performed.
3. Patients with inflammatory bowel disease with suspected abscess, fistulas, or sinus tract formation.

Although controversial, iodine agents also help in speeding up the intestinal transit time because they produce transfer of water into the lumen owing to their hyperosmolarity.³⁹⁴ However, these agents should be used with caution in patients at high risk for vomiting and aspiration because they have an added toxic and hyperosmotic effect on the pulmonary lining.

Air-density contrast agents can be used alone or as an adjunct to high-density or fat-density contrast agents. In the stomach, carbon dioxide gas is delivered by effervescent granules that have been used during the upper GI series. In the colon, air is insufflated via a rectal tube. These techniques with the use of air or gas not only produce reliable distention and discrimination of the viscus from adjacent structures but also help in assessing the true thickness of the bowel wall (Fig. 34-2).^{394, 623}

Wide window settings are required for accurate assessment of the bowel wall thickness. The normal width of the bowel wall is thinner when air-contrast techniques are used, and this feature may therefore increase the sensitivity of CT in detecting GI disease.⁶²³ However, several drawbacks are noted in the air technique; changes in patient positioning, glucagon for bowel relaxation, and fast scanning to avoid artifact are required.⁶²³ In addition, this technique has the potential for obscuring the discrimination between intraluminal and extraluminal air collections.

Although not commonly used, fat-density agents can be applied for local staging and follow-up study of rectal tumors and assessment of diverticulitis.⁴⁹⁴ However, cau-

tion should be exercised in patients with severe, symptomatic gallbladder disease or acute pancreatitis; fulminant or complicated inflammatory bowel disease; and suspected cysts, pseudocysts, abscess formation, and cystic masses.⁴⁹⁴

In addition to air-density and fat-density agents, the administration of water is used as a negative agent in some institutions, especially for demonstrating pathology in the stomach and rectum. Water has some advantages: it may be the most tolerable agent to the patients, and it produces excellent mural visualization without beam-hardening, motion, or other streak artifacts.

Bowel Wall Patterns

Inflammatory Diseases

The hallmark of most inflammatory bowel diseases on CT scans is symmetrical and circumferential bowel wall thickening, usually not exceeding 1.5 cm.²⁶³ However, an asymmetrical pattern of bowel wall thickening is also commonly seen in chronic forms of inflammatory bowel diseases (e.g., Crohn's disease, intestinal tuberculosis [TB]) because cicatricial and fibrotic changes do not always occur circumferentially. The degree of bowel wall thickening depends primarily on which intestinal layers—mucosa, submucosa, muscularis propria, or serosa—are predominantly affected by the inflammatory process. Inflammatory processes confined to the mucosa or to the superficial layers of the bowel wall may not be displayed reliably on CT scans unless the full thickness of the bowel wall is involved. Bowel wall thickening results from a variety of pathologic processes occurring in several layers of the intestinal wall, including the following:

1. Transmural granulomatous infiltration with edema, fibrosis, inflammation, and lymphangiectasis in Crohn's disease.
2. A combination of infiltration of the lamina propria by round cells, hypertrophy of the muscularis mucosa, and deposition of submucosal fat in ulcerative colitis.¹⁹²
3. Muscle hypertrophy, fibrosis, edema, intramural inflammation, or organized intramural inflammatory mass in diverticulitis.²⁴
4. Edema and necrosis in neutropenic colitis.¹⁷¹

Except for certain cases in which the predominant pathologic processes in the intestinal wall result from hematoma or fat accumulation, CT may not clearly determine their primary pathologic process. The stages of the inflammatory process may also affect the degree of thickening, which is more severe in the acute stage than in the chronic stage, because an acute process frequently accompanies the edematous components associated with mucosal ulcerations.

Although some differences are noted in the degree of bowel wall thickness in various inflammatory bowel diseases, bowel wall thickness alone cannot be used as an absolute indicator to establish a specific diagnosis. In certain instances, contrast enhancement patterns of the involved bowel wall, rather than bowel wall thickness, are more helpful for determining the diagnosis. Abnormally thickened bowel wall may enhance homogeneously or

Figure 34-2. CT scan after air insufflation into the rectum.

show heterogeneous enhancement with a double-halo sign (two rings) or target sign (three rings). The double-halo or target sign is mainly caused by accumulation of edematous fluid, hemorrhage, lymph, or fat predominantly in the submucosa. If these signs are demonstrated, there is a greater chance of a chronic rather than an acute inflammatory process.¹⁹

Although these signs are helpful in detecting GI tract abnormalities, they are, unfortunately, not specific for a particular type of disease process. Until recently, it has been generally agreed that the presence of these signs indicates non-neoplastic disease because the signs occur in various inflammatory and vascular disorders (Crohn's disease, ulcerative colitis, pseudomembranous colitis, radiation enterocolitis, eosinophilic gastroenteritis, ischemic bowel diseases, amyloidosis, portal hypertensive colopathy). However, one series has shown that these signs can be seen in a neoplastic process in which abundant fibrosis accumulates in the submucosal layer of the GI tract, especially in patients with metastasis to the GI tract from gastric cancer²⁰⁵ or *signet ring* cell type of colorectal cancer.²⁹⁰ In addition, the thickness and enhancing degree of each layer in the double-halo or target sign appear to differ from case to case or even in patients with the same disease entity. Further morphologic investigation of the target appearance on CT scanning would help discriminate inflammatory, ischemic, and neoplastic diseases.

Another characteristic pattern of bowel wall thickening—the *accordion sign*—represents alternating edematous haustral folds separated by transverse mucosal ridges filled with oral contrast material. This sign has been described in the literature as a highly suggestive finding for pseudomembranous colitis¹⁵⁶ and is demonstrated in 4% to 19% of patients with documented pseudomembranous colitis.⁴³² However, some reports suggest that this sign is also nonspecific and occurs in other conditions such as portal hypertensive colopathy,²⁵² ischemic colitis, and cytomegalovirus (CMV) colitis.⁴²⁰ Therefore, the accordion sign should be viewed as indicative of severe colonic edema of uncertain cause.

In addition to bowel wall thickening patterns, observing the length and multiplicity of the involved segment helps to differentiate inflammatory from neoplastic and vascular diseases as well as narrow the range of differential diagnoses among inflammatory bowel diseases. Generally, in the acute stage of inflammatory bowel disease, the length of the involved segment is longer than in neoplastic diseases (<10 cm) but is shorter than in vascular diseases. In the chronic stage, when strictures and fibrosis develop, the involved bowel length becomes much shorter than in the acute stage, thereby simulating neoplastic conditions. Although multiplicity is also more commonly seen in inflammatory bowel diseases, it occurs in some neoplastic diseases, such as lymphoma of the Mediterranean type involving the small intestine and metastatic neoplasm as well as in vascular diseases such as vasculitis.²¹³

It is well known that the appearance of a transition zone between the involved and normal segments is important in distinguishing inflammatory from neoplastic conditions on barium study. This finding can also apply to CT interpretation and is useful in differentiating diverticulitis from colonic carcinoma. Although abrupt transition is characteris-

tic of neoplastic diseases, a tapered appearance is a common manifestation of inflammatory diseases.

Neoplastic Diseases

Benign tumors of the small and large intestine include adenomas, lipomas, stromal tumors, hamartomas, fibromas, and hemangiomas. Malignant tumors include adenocarcinomas, lymphomas, sarcomas, and carcinoids. The hallmark of a GI neoplasm on CT is eccentric or asymmetrical wall thickening or mass formation in the bowel; bowel wall thickening usually exceeds 1.5 cm.²⁶³ However, a circumferential pattern of bowel wall thickening can also be seen in neoplastic processes, such as lymphoma, as well as primary and metastatic neoplasms. In certain instances, a mass with a large central cavitation is thought to be a lesion having circumferentially thickened bowel wall owing to misinterpretation of large central cavitation as bowel lumen.

The length of intestine involved in the neoplastic process is usually short (<10 cm), except for cases of infiltrative type of lymphoma, signet ring cell colorectal carcinoma, and linitis plastica type of metastatic neoplasm.²⁰⁵ Multifocal involvement of the bowel is a common manifestation of lymphoma, lipoma, and metastatic neoplasm. As mentioned earlier, the transition zone to the normal segment is abrupt.

When neoplasms form a mass, the tumor margins are usually smooth in benign neoplasms and lobulated, irregular, or spiculated in a malignancy. Although masses with a diameter smaller than 2 cm may be missed by CT scanning,³¹⁵ most polypoid or pedunculated mucosal or submucosal masses are detected incidentally by intussusception with small-bowel obstruction. Exophytic tumor growth is favored by some GI neoplasms, including GI stromal tumors, lymphomas, and metastatic melanomas. However, gastric or colonic adenocarcinomas rarely show such behavior. In a series by Lee and associates,³¹⁷ the presence of gastric wall thickening adjacent to an exophytic mass favors the diagnosis of exophytic adenocarcinoma rather than GI stromal tumor.

Analyzing the internal constituents of a mass is helpful in establishing a specific diagnosis. The presence of fat within a mass on a CT scan is a pathognomonic finding for lipoma or liposarcoma. When tumors show internal hemorrhage within a mass that is easily detectable on unenhanced CT, the differential diagnosis includes GI stromal tumor and metastatic melanoma. CT is also useful for detecting internal calcification of a mass. This is most commonly seen in mucinous adenocarcinoma and in GI stromal tumors,⁹³ but other possibilities include neurogenic tumors, carcinoid and adenocarcinoma, or lymphoma treated with chemotherapy or radiation.

Knowing a lesion site is also useful in the differential diagnosis when neoplasm is suspected on CT. In adenocarcinoma of the small intestine, 42% of the locations are in the duodenum, whereas more than 35% involve the proximal jejunum. Lymphomas primarily affect the ileocecal region in children and young adults, but lymphomas complicating celiac disease usually involve the proximal jejunum.

Ninety percent of carcinoid tumors are located in the

ileum.⁶⁴ The malignant form of GI stromal tumors occurs with equal frequency in the jejunum or ileum, whereas the jejunum is more common in the benign form. The colon is a rare site of GI stromal tumors, but when these tumors develop in the colorectum, the most common site is the rectum.²⁸⁷ Most lipomas are located in the ileum or the ileocecal valve.

A contrast enhancement study not only helps to characterize the tumor but also determines the extent of tumor in the GI tract. Contrast enhancement of the soft tissue mass may depend on the desmoplastic response, its vascularity, and the degree of tumor necrosis. One of the typical tumors eliciting a desmoplastic response is scirrhous gastric cancer²⁸ or signet ring cell carcinoma of the stomach or colorectum. Because these tumors produce abundant fibrosis in the submucosal layer of the GI tract, they are well enhanced after contrast agent infusion. In contrast, lymphomas that do not elicit a desmoplastic response enhance poorly.³⁴³ The accumulation of intracellular or extracellular mucin also affects the degree of contrast enhancement. Thus, mucinous adenocarcinomas are also poorly enhanced.⁴¹³

Vascular Diseases

Mesenteric ischemia occurs in a variety of conditions, including thromboembolism, bowel obstruction, neoplasm, vasculitis, inflammatory bowel diseases, and trauma and as a result of drug or radiation therapy.⁵⁰¹ Hypoperfusion (low-flow state) of the blood flow is also one of the most common causes of bowel ischemia.

The hallmark of a vascular disorder on CT is concentric bowel wall thickening; the thickness usually does not exceed 1.5 cm. The bowel wall becomes much more thicker in mesenteric ischemia caused by mesenteric venous occlusion than in ischemia of arterial origin. However, intestinal ischemia is not always seen with bowel wall thickening. This is partially the result of the inherent limitation of CT for detecting subtle bowel wall thickening. Moreover, bowel wall is thinned or occasionally invisible when the involved segments become gangrenous. A delayed diagnosis of intestinal ischemia is occasionally encountered in cases having normal-appearing or thinned bowel wall.

A thickened bowel wall is commonly associated with target or double-halo signs owing to the accumulation of edematous fluid or hemorrhage in the submucosal layer of the intestine. Although these signs are nonspecific, close observation of these signs in patients with mesenteric ischemia may help to determine the presence or absence of irreversible changes in the GI tract. For example, diffuse disruption of these signs or discontinuity of the outer (serosal) layer may suggest the presence of irreversible bowel changes.

Target or double-halo signs are also helpful in distinguishing whether bowel ischemia originates from thromboembolism or vasculitis.²⁸ Although the cause is unclear, the target signs in patients with vasculitis are much more clearly layered than in those with thromboembolism.⁷⁰

Intramural or superior mesenteric or portal vein gas is also occasionally demonstrated in the ischemic segments. However, the presence of intramural gas does not always indicate mesenteric ischemia because it can be seen in

patients with pulmonary disease, peptic ulcer disease, collagen vascular disease, steroid administration, and intestinal obstruction.^{97, 403}

In contrast to cases of mesenteric ischemia, Behçet's syndrome (a nonspecific necrotizing vasculitis involving multiorgan systems) shows concentric bowel wall thickening or polypoid mass formation on CT²¹²; the masslike lesion develops because of marked thickening of the intestinal wall surrounding the large ulceration.

When cases of inflammatory and neoplastic bowel disease are compared, one of the most characteristic CT features of intestinal ischemia caused by frequently encountered thromboembolism is the continuity and segmental distribution of involved segments; ischemic bowel is generally confined to the mesenteric vascular territory. In contrast, nonsegmental distribution and multifocal involvement are characteristics of mesenteric ischemia associated with multiple thromboemboli, vasculitis, and drug or radiation therapy.⁵⁰¹ In addition, ischemia proximal to obstructing colonic carcinoma also causes nonsegmental type of distribution, thus helping detect small, hidden malignancy on CT.

Although the length of the involved segment is usually long in mesenteric ischemia caused by thromboembolism, length depends on the levels of vascular occlusion in the mesenteric vessels; the segment is very short when the vasa recta or intramural vessels are occluded and is very long when the proximal main branches are involved. The end result of mesenteric ischemia may be normalization of the intestinal wall, bowel perforation, or stricture formation. In cases of intestinal stricture formation, the involved bowel is very short, simulating adenocarcinoma or stricture caused by chronic inflammatory bowel disease such as Crohn's disease or intestinal TB.

There are preferential sites for certain types of intestinal ischemia. For example, the duodenum and rectum, which are supplied by abundant blood flow, tend not to develop ischemia caused by thromboembolism. However, these sites are a common location of vasculitis; we presume that immune complex deposition occurs more commonly at sites of increased blood flow.²⁹²

In radiation enterocolitis, the involved site is confined to the radiation port. Post-traumatic stricture resulting from focal deprivation of mesenteric blood supply resulting from a tear in the mesenteric attachment commonly occurs near the proximal or distal extreme of the small intestine where mesenteric mobility commences.³⁷³ Intestinal ischemia proximal to a colonic carcinoma develops at sites that are vulnerable to increased intraluminal pressure caused by bowel distention.^{51, 248} According to the application of *Laplace's law*, tension in the bowel wall increases with both increasing intraluminal pressure and increasing diameter of the obstructed bowel.

Contrast enhancement patterns of vascular disorder, especially mesenteric ischemia, are characteristic. The ischemic segments are not enhanced or are poorly enhanced in the early phase²⁰⁸ but demonstrate prolonged enhancement in the late phase.⁶²⁰ These enhancement patterns result from perfusion problems associated with the ischemic segment (i.e., delayed return of the venous blood, with subsequent slowing of the arterial supply in mesenteric venous occlusion and arteriospasm in arterial occlusion). Poor contrast

enhancement or an absence of contrast is reported to be one of the most valuable findings in differentiating simple from strangulated intestinal obstruction, although its sensitivity is not high (34%).²⁰⁸

Perigastric, Perienteric, or Pericolonic Changes

Inflammatory Diseases

CT is useful for defining various mesenteric, perienteric and pericolonic abnormalities that commonly occur in inflammatory diseases. Bowel separation is a common finding in Crohn's disease on barium study regardless of the primary cause. CT clearly determines the causes of bowel separation, such as fibrofatty proliferation, abscess formation, phlegmonous changes, and lymphadenopathy. In patients with ulcerative colitis, CT helps to define the causes of widening of the presacral space, such as increased fat deposition, inflammatory infiltration of perirectal fat, or rectal wall thickening.

Although observing mucosal changes is important in identifying GI diseases, differentiating Crohn's disease from intestinal TB is not always easy with barium study, which is the only reliable radiologic tool for assessing mucosal detail. However, observing perienteric or peritoneal changes on CT scans may occasionally yield clues for resolving the difficulty. The presence of partially calcified, enlarged lymph nodes with low-attenuation centers caused by central caseation necrosis is the most diagnostic finding in intestinal TB. Other findings favoring a diagnosis of intestinal TB include diffuse infiltrations in the omentum and mesentery and multiple enlarged nodes larger than 1 cm; the latter finding is unusual in cases of Crohn's disease (usually 3 to 8 mm) if lymphoma or adenocarcinoma is not a complication.¹⁸⁸ In contrast, the incidence of fibrofatty proliferation is much higher in Crohn's disease.

There are several GI diseases in which the presence of inflammatory infiltrates in the perienteric or pericolonic fat adjacent to the bowel is crucial for making a specific diagnosis. The most typical cases in such circumstances include acute appendicitis, primary epiploic appendagitis, and diverticulitis. The definitive diagnosis of *acute appendicitis* is made on CT images by identifying a combination of abnormal-appearing appendix (>6 mm in diameter or nonopacified), periappendiceal inflammatory infiltrates, and a calcified appendicolith.^{487, 490} In the absence of abnormal thickening of the appendiceal wall or periappendiceal inflammation, the presence of calcific appendicoliths or air is not clinically significant. Periappendiceal inflammatory changes without evidence of abnormal appendix or appendicolith is a suggestive but nonspecific finding because such conditions can occur in a variety of pathologic conditions (Crohn's disease, typhlitis, diverticulitis, pelvic inflammatory disease, and perforated carcinoma).

Primary epiploic appendagitis is a rare inflammatory intra-abdominal process attributable to either torsion or spontaneous venous thrombosis of an epiploic appendage with subsequent ischemic infarction and inflammation.⁵⁷⁵ CT findings are virtually pathognomonic for establishing the diagnosis, and they include a pericolonic, oval-shaped

lesion with fat attenuation, thickened visceral peritoneal lining, and pericolic fat stranding.^{489, 504}

Diverticulitis results from diverticular perforation with resultant intramural, pericolic, or peritoneal inflammation. On CT, diagnostic findings include the presence of pericolic inflammation and edema, appearing as regions of linear stranding or hazy increased density in the pericolonic fat adjacent to the site of diverticular perforation. In more severe cases, pericolonic phlegmon or abscess may be present.

In the clinical setting, the differentiation of diverticulitis from colonic cancer is crucial for appropriate clinical management. Balthazar and colleagues²⁴ reported that the imaging appearances overlapped in about 10% of cases. Some researchers have stressed the importance of observing pericolonic or perienteric and mesenteric changes.^{86, 87} The incidence of pericolonic lymphadenopathy is much higher in patients with colonic cancer than in patients with diverticulitis, whereas CT findings of fluid at the root of the mesentery and vascular engorgement are much more common in patients with diverticulitis.⁴⁴⁶

Neoplastic Diseases

In a patient with neoplastic disease, distinguishing the depth of tumor invasion in the bowel wall cannot be made with CT. Therefore, observing perigastric or pericolonic or perigastric changes may be essential for staging gastric or colorectal cancers; the margin of the stranding in neoplastic diseases generally appears sharper than that of inflammatory bowel diseases.

Extension of tumor beyond the bowel wall is suggested when the outer borders of involved bowel wall are irregular along with soft tissue or linear strandings in the pericolonic or perigastric fat plane. However, use of these CT signs in staging the tumors has been limited. It is because CT is not sensitive enough to detect microscopic invasion of the adjacent fat. Therefore, a sharp outer border of the bowel wall without strands in the adjacent fat cannot exclude the possibility of tumor extension beyond the bowel wall. Moreover, vascular or lymphatic congestion, coexisting inflammatory changes, acute and chronic radiation changes, or paucity of fat caused by cachexia may produce extraluminal changes similar to those of tumor infiltration.

In addition, *carcinoid tumor* is one of the neoplastic diseases in which CT features provide a reliable and specific diagnosis by revealing the mesenteric change. On CT, these tumors show linear or curvilinear soft tissue strands in the mesenteric fat, radiating from the primary mass to the displaced and angular bowel loops.⁴⁶⁵

Vascular Diseases

In patients with suspected mesenteric ischemia, perienteric or pericolonic changes appear to be somewhat different from those in inflammatory and neoplastic diseases. The presence of both diffuse mesenteric haziness and vascular engorgement is the hallmark of vascular diseases that have outflow disturbance of mesenteric blood flow caused either by mesenteric or portal venous occlusion or by increased mesenteric or portal venous pressure. In contrast, cases of *mesenteric arterial occlusion*, a disorder with inflow disturbance of the mesenteric vessels, do not show mesen-

teric engorgement. In most patients with mesenteric inflow disturbance, however, collateral circulations develop in the mesentery, retroperitoneum, or both. Unfortunately, CT does not clearly discriminate whether increased mesenteric vessels indicate mesenteric engorgement or abundant collateral circulation. Therefore, it is important to scrutinize the presence of thromboembolism in mesenteric vessels if the mesenteric vessels are increased in number, if the diameter or mesenteric haziness is seen, and if advanced liver cirrhosis, which causes increased mesenteric and portal venous pressure, is excluded.

In patients thought to have small-bowel obstruction due to bowel adhesions and bands, volvulus, and hernia, observing mesenteric vascular changes is important to distinguish simple from strangulated intestinal obstruction. Although the presence of severe mesenteric haziness and vascular engorgement favors the diagnosis of strangulated obstruction,²⁰⁸ a mild degree of such vascular changes is also demonstrated in simple obstruction. However, one may have difficulty in determining the degree of these vascular changes with CT. Accordingly, the signs of mesenteric vascular engorgement and haziness should be interpreted cautiously on CT scans in patients for whom the decision of simple from strangulated intestinal obstruction is critical.

An unusual mesenteric vascular course, such as mesenteric vascular twisting (*whirl sign*), is also known to be highly specific for the diagnosis of strangulated obstruction.²⁰⁸ This sign was originally reported in patients with intestinal malrotation associated with volvulus.¹⁵⁴ The whirl sign can also be seen in asymptomatic patients who have

undergone gastrectomy with surgical maneuver of the small intestine.

Although mesenteric vascular changes are more commonly seen in patients with vascular disorders, a small group of patients with inflammatory bowel disease, such as Crohn's disease, shows hypervascularity in the perienteric or pericolic spaces or in the mesentery. This hypervascularity is found in the earlier or active stages of Crohn's disease rather than in the chronic stages.³⁵⁸ Even though the cause of this finding is not well understood, some researchers hypothesize that hypervascularity is the result of vasculitis with hypercoagulability leading to ischemia,⁵⁹¹ and more recent studies have demonstrated an increased expression of somatostatin receptors in the veins of inflamed intestine.⁴⁹⁸ In addition, because bowel ischemia can develop in the colon proximal to cancers, a small tumor can be missed if pericolic vascular engorgement and haziness due to coexisting colonic ischemia are prominent.

Esophagus

Techniques and Anatomy

The esophagus extends from the pharynx to the cardia of the stomach. It is 20 to 25 cm in length and distends up to 30 mm in breadth but is collapsed at rest.⁴⁴¹ It may be divided into three parts:

1. The *cervical* segment is located near the midline and is posterior to the trachea.

Figure 34-3. Normal esophagus. The cervical (A) and thoracic (B) segments (arrows) of normal esophagus appear as well-defined circular structures of soft tissue on this CT scan.

2. The *thoracic* segment is the longest and lies behind the trachea until the trachea bifurcates.
3. The *abdominal* segment is the shortest segment; it is only a few centimeters in length, escapes the diaphragmatic hiatus, and runs to the cardia of the stomach.

On CT, the esophagus appears as a well-delineated circle of soft tissue (Fig. 34-3). Although the wall thickness of the collapsed esophagus has no absolute normal size, a well-distended esophagus should not exceed 3 mm in wall thickness,^{495, 525} and eccentric thickening of the wall should suggest a pathologic condition.²¹⁸ An anteroposterior diameter of the esophagus larger than 16 mm and a lateral diameter larger than 24 mm are considered abnormal, although they may increase with advancing age (Fig. 34-4). A small amount of air in the esophagus is visible in approximately 65% of normal individuals, but an air-fluid level, fluid-filled lumen, or lumen caliber higher than 10 mm usually indicates obstruction or severe esophageal dysmotility.^{380, 395, 417}

With magnetic resonance imaging (MRI), the normal esophagus is routinely well visualized in the upper thoracic and gastroesophageal regions (Fig. 34-5), whereas the middle portion of the esophagus is flattened behind the left atrium, sometimes making its visualization difficult.³⁹⁵ The MRI appearance of normal esophageal wall is a low-signal-intensity structure, well defined by high signal intensity of periesophageal fat on T1-weighted images. The normal esophagus also appears with low signal intensity contrasted with high signal intensity of internal contents on T2-weighted image. After administration of IV gadolinium diethylene triaminepentaacetic acid (Gd-DTPA), the muscle layer of the esophagus shows moderate enhancement.^{475, 528}

Figure 34-4. Normal esophagus of a 77-year-old man. The lumen of the esophagus (E) is somewhat dilated; however, in older people, mild air-filled dilatation of the esophagus is regarded as a normal condition.

Benign Tumors

Benign tumors of the esophagus are not a common condition, and they contribute about 20% of esophageal neoplasms.³⁵⁰ Depending on the site of origin, benign esophageal tumors comprise mucosal and submucosal lesions. On CT or MRI, small lesions cannot be demonstrated, so that barium study appears to be superior to cross-sectional image in providing information about small lesions.

Leiomyoma (Stromal Tumor)

The stromal tumor of the esophagus is the most common benign esophageal tumor, accounting for more than 50% of all benign esophageal tumors.⁴⁴⁶ Histologically, it is characterized by proliferation of smooth muscle and is most frequently located in the distal third of the esophagus (60%), followed by the middle third (30%) and the proximal third (10%).⁵³³ Most patients are asymptomatic, but some may present with dysphagia, depending on the size of the lesion and how much it encroaches on the lumen. Although most esophageal stromal tumors occur as a solitary lesion, multiple lesions are present in 3% to 4% of patients; the lesion is often associated with Alport's syndrome in children.^{185, 477}

Occasionally, stromal tumors arising near the gastroesophageal junction may involve not only the distal esophagus but also the gastric cardia and fundus.⁵³⁰ In this location, these tumors may cause severe dysphagia due to obstruction of the distal esophagus, and it may be difficult to distinguish them from carcinoma of the cardia involving the distal esophagus.

On CT, a stromal tumor appears as an intraluminal mass or as eccentric or concentric esophageal wall thickening, which usually shows homogeneous soft tissue attenuation (Fig. 34-6) and in rare instances may contain irregular calcifications (Fig. 34-7). The peripheral margins of the lesion are usually smooth, and the surrounding mediastinal fat planes are intact.^{380, 399} Sometimes CT appearances of stromal tumor are nonspecific and indistinguishable from those of a localized malignant tumor. In leiomyomatosis, CT reveals marked circumferential or eccentric wall thickening of the distal esophageal wall with soft tissue attenuation. In addition, CT may occasionally show a mass bulging into the gastric fundus or uncharacteristic achalasia associated with distal esophageal wall thickening.^{337, 477}

Fibrovascular Polyp

Fibrovascular polyp of the esophagus is a rare, benign intramural tumor that is composed of loose or dense fibrous tissue, adipose tissue, and a vascular structure. The polyp is covered by normal squamous epithelium. It usually develops from the upper third of the esophagus near the level of the cricopharyngeus. This lesion probably originates from the loose submucosal tissue of the cervical esophagus, gradually elongating over a period of years as the polyps are dragged into the middle or distal third of the esophagus by esophageal peristalsis until the intraluminal portion of the lesion becomes massive.^{11, 30, 78, 339, 600}

These polyps usually occur in elderly men. Common symptoms include long-standing dysphagia, vomiting,

Figure 34-5. MR images of normal esophagus. *A*, On the T1-weighted image, the signal intensity of normal esophageal wall (arrowheads) is low. *B*, On the T2-weighted image, the signal intensity of the esophageal wall (arrowheads) is also low, contrasted with internal contents of high signal intensity. *C*, After administration of gadolinium-DTPA, esophageal wall (arrowheads) shows moderate enhancement.

weight loss, and respiratory difficulty. Occasionally, fibrovascular polyps with a long stalk can be regurgitated into the pharynx or mouth, resulting in sudden death from laryngeal occlusion.^{11, 78} Small lesions can be removed endoscopically, but larger masses should be excised surgically because of the potential for hemorrhage.

CT shows a wide spectrum of attenuation from fat to soft tissue, depending on the amount of adipose and fibrovascular tissue in the polyp.³³⁹ If adipose tissue content

predominates, intraluminal esophageal mass with fat attenuation is considered as a typical CT sign of a fibrovascular polyp.¹¹ In addition, CT may help to determine the intraluminal location of the lesion, particularly when oral contrast material surrounds a mass.

MRI demonstrates a lipid-containing substance, mucoid secretion, and nonacute blood within the tumor; on T1-weighted images, high signal intensity is present, and on

Figure 34-6. Leiomyoma of the esophagus. CT scan shows an eccentric mass (arrowheads) of the esophagus at the level of the carina. The lesion shows a smooth margin and homogeneous soft tissue attenuation.

Figure 34-7. Calcified leiomyoma of the esophagus. CT scan demonstrates concentric wall thickening (arrowheads) of the gastroesophageal junction. This lesion contains multifocal calcifications (arrows).

T2-weighted images, soft tissue and muscle within the tumor display low signal intensity. In addition to defining tissue composition, MRI is helpful in defining the spatial location of the mass with the use of multiplanar images.^{11, 78}

Hemangioma

Hemangioma of the esophagus is a rare, benign tumor that has been reported in fewer than 5% of all esophageal benign tumors.⁴¹⁴ Although the pathogenesis of this neoplasm is still controversial, most agree that hemangioma is a vascular hamartoma or tumor-like malformation.¹⁹³ The most common symptoms include hemorrhage and dysphagia. Other minor symptoms are epigastric pain, chest pain, retrosternal pain, weight loss, choking, and melena.¹⁹³

On CT, hemangioma shows a well-defined homogeneous mass with soft tissue attenuation, occasionally containing a small calcification regarded as a phlebolith. After administration of a contrast agent, significant enhancement is usually present, indicating high vascularity; in atypical cases, however, enhancement may be poor.^{447, 581} With MRI, hemangioma of the esophagus is manifested as an isointense mass on T1-weighted images and as a hyperintense mass on T2-weighted images. Both fibrosis and reduction of blood flow in the hemangioma may raise the signal intensity on T1-weighted images.⁵⁸¹

Esophageal Carcinoma

Most malignant neoplasms of the esophagus are squamous cell carcinoma and/or adenocarcinoma. Other rare malignant tumors include spindle cell carcinoma, small-cell carcinoma, malignant stromal tumor, Kaposi's sarcoma, and malignant melanoma. Although squamous cell carcinoma contributes to most cases of esophageal cancer, adenocarcinoma has recently been found to be the predominant type in patients with newly diagnosed esophageal carcinoma, and Barrett's esophagus is seen in many of these patients.^{299, 335, 341}

Various terms have been used to describe the status of esophageal carcinoma,³⁷² for example:

Early esophageal cancer, limited to the mucosa or submucosa without lymph node metastasis

Superficial spreading cancer, limited to mucosa or submucosa with or without lymph node metastasis

Small esophageal cancer, in which the tumor size is less than 3.5 cm, regardless of the depth of invasion and the presence or absence of lymph node metastasis

CT and MRI have been used to stage esophageal carcinoma, because these techniques can reveal extraesophageal extension into adjacent mediastinal structures, including the trachea, bronchi, aorta, and pericardium, and can detect lymphadenopathy in the mediastinum. The main goal of staging is to identify nonresectable lesions and thereby avoid the morbidity of major surgery in patients who would not benefit from such intervention.^{221, 417}

Squamous Cell Carcinoma

Squamous cell carcinoma of the esophagus has been thought to occupy about 90% of cases of primary esopha-

geal malignancy. The incidence of this tumor is variable according to geographic location, with the highest incidences in China, Iran, and South Africa.^{148, 428} In the United States, tobacco and alcohol are the two major risk factors; other predisposing factors include achalasia, lye strictures, head and neck tumors, celiac disease, Plummer-Vinson syndrome, and tylosis.⁶⁰⁹

Dysphagia and weight loss are the classic presenting symptoms of squamous cell carcinoma. When dysphagia develops, the esophageal lumen has been already reduced by more than 50% of its normal caliber and approximately two thirds of the circumference of the esophageal wall is invaded by the tumor.^{189, 335, 609} Ulceration in the tumor may produce odynophagia, and patients may have chest pain unrelated to swallowing if the tumor has invaded the mediastinum.

Squamous cell carcinoma may directly invade the adjacent structures involving the trachea, bronchi, lungs, pericardium, aorta, and diaphragm and may spread to lymph nodes in the mediastinum, neck, and upper abdomen. This tumor can also readily metastasize to the lungs, liver, adrenal glands, and other structures through the bloodstream.³⁴¹

Adenocarcinoma

The most important predisposing factor in development of adenocarcinoma of the esophagus is Barrett's esophagus, of which 40% of cases progress to esophageal adenocarcinoma, called *Barrett's carcinoma*.^{84, 144, 299, 335, 341, 342, 372, 417} In patients with Barrett's esophagus, the normal squamous epithelium in the distal esophagus is transformed to columnar epithelium, presumably as a result of chronic reflux disease, with the columnar epithelium extending more than 2 cm above the esophagogastric junction. Unlike squamous cell carcinomas, which tend to occur in the upper mid-esophagus, two thirds of adenocarcinomas arising in Barrett's esophagus are located in the distal esophagus and tend to invade the gastric cardia and fundus.³⁴¹ At present, 50% of the tumors at the gastroesophageal junction are thought to be Barrett's carcinoma that is invading the stomach.⁴¹⁷

Patients with esophageal adenocarcinomas typically present with recent onset of dysphagia and weight loss. Like squamous cell carcinoma, unfortunately, by the time dysphagia has occurred, tumors are usually advanced, so that the prognosis is poor. Moreover, the adenocarcinoma does not respond to chemotherapy and radiation therapy, as does the squamous cell carcinoma.^{335, 372} Many investigators advocate endoscopic surveillance of asymptomatic patients with known Barrett's esophagus to detect the dysplastic changes prior to the development of overt carcinoma. Occasionally, early adenocarcinomas can also be detected fortuitously in patients with underlying reflux disease.

Staging

The accurate pretreatment staging of esophageal cancer is important because it determines the operability and the goal of operation, that is, whether treatment will be curative or palliative. The *Tumor-Node-Metastasis (TNM) classification*, in which esophageal tumors are specified according to extent of tumor spread, nodal involvement, and distant

Table 34–1. TNM Staging System for Esophageal Cancer

T—Primary Tumor	N—Regional Lymph Nodes	M—Distant Metastasis
Tis Carcinoma in situ	N0 No regional nodes	M0 No distant metastasis
T1 Tumor invades mucosa or submucosa	N1 Regional nodal metastasis*	M1 Distant metastasis†
T2 Tumor invades muscularis propria		
T3 Tumor invades adventitia		
T4 Tumor invades adjacent structures		

* Regional lymph nodes include cervical, mediastinal, and perigastric nodes.

† Celiac lymph node metastasis is regarded as N1 in adenocarcinoma; however, it is regarded as M1 in squamous cell carcinoma.

metastasis, is the most widely accepted system of staging for esophageal cancer (Tables 34–1 and 34–2).^{189, 521} TNM staging for both squamous cell carcinoma and adenocarcinoma is similar with minor exceptions in staging related to regional and distant nodal metastases. The criterion for N1 regional nodal metastases for squamous carcinoma includes involvement of cervical, mediastinal, and perigastric nodes. The presence of celiac lymph node metastases in squamous cell carcinoma, however, is classified as M1 (i.e., distant metastasis) versus N1 (i.e., regional nodal disease) for esophageal adenocarcinoma.^{521, 580}

Although many investigators have evaluated and compared the usefulness of CT and MRI in staging esophageal carcinoma, controversies remain about which imaging modality is superior. In clinical situations, CT is usually recommended as a routine examination before treatment planning, and CT staging criteria correspondent to the TNM staging system have been proposed by some investigators.^{464, 576} Whichever modality is used to stage esophageal carcinoma, the extent of involvement of the esophageal wall by tumor, invasion of adjacent structures, and metastasis of disease to regional nodes or distant organs is the major issue for the radiologist.

Tumor Staging

On CT scans, esophageal carcinoma appears as a mass or wall thickening with soft tissue attenuation. With MRI, esophageal carcinoma is seen as an area of isointensity relative to residual esophageal wall on T1-weighted images and as an area of high signal intensity on T2-weighted images.⁵⁶³ The depth of tumor infiltration into the esophageal wall, one of the most important prognostic factors, can best be evaluated by endoscopic ultrasonography, which can directly visualize all layers of the esophageal wall.²⁴⁰

Compared with endoscopic ultrasonography, CT and

MRI are not reliable tools for evaluation of the extent of the tumor in the esophageal wall because they cannot definitively demonstrate the individual layers of the wall. Therefore, CT and MRI cannot differentiate T1 from T2 tumor.⁴⁵⁹ In one series in which specimens of esophageal carcinoma were examined with 4.7 T, MRI demonstrated all layers of the esophageal wall, which correlated with pathologic examination.⁶¹⁰ In the future, technical development in imaging modality may improve the ability of CT or MRI to delineate these layers.

Macroscopic periesophageal fat invasion by the tumor can be demonstrated with high accuracy on CT and MR images, although microscopic invasion to periesophageal fat is not revealed.^{102, 459} On CT scans, periesophageal fat invasion is shown as strandlike areas of soft tissue attenuation that generate a feathery appearance within the periesophageal fat plane (Fig. 34–8).⁴¹⁷ MRI shows periesophageal fat invasion as having an ill-defined, irregular margin, regional absence of a bright fat signal, and tumor mass into the adjacent mediastinal fat.^{240, 610} The overall accuracy of periesophageal fat invasion of esophageal carcinoma

Figure 34–8. Esophageal cancer invading mediastinal fat. CT scan demonstrates circumferential wall thickening of the distal esophagus (arrow). The periesophageal fat is replaced by soft tissue attenuation (arrowheads).

Table 34–2. Stage Grouping of Tumor-Node-Metastasis (TNM) Classification

Stage Grouping	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
IIA	T2	N0	M0
	T3	N0	M0
IIB	T1	N1	M0
	T2	N1	M0
III	T3	N1	M0
	T4	N0–1	M0
IV	T1–4	N0–1	M1

on CT or MRI ranges from 88% to 100%.²⁴⁰ Although periesophageal fat infiltration adversely affects prognosis, it is not a contraindication to en bloc resection of tumor as a curative treatment.⁴¹⁷

Accurate evaluation of tracheobronchial, aortic, and bone invasion is important because these are contraindications to surgical resection. The most frequent sites of tracheobronchial involvement are the distal trachea and the left mainstem bronchus.¹⁰⁸ CT or MRI appearances of tracheobronchial invasion are displacement or indentation of the posterior wall of the trachea or the bronchus by tumor mass as well as evidence of direct extension of the tumor into the lumen of the airway (Fig. 34-9). Reported data indicate that the overall accuracy of tracheobronchial invasion of esophageal carcinoma ranges from 88% to 97%.²⁴⁰ The absence of an intervening fat plane alone, however, does not always suggest tumor invasion because this finding can be seen in normal patients.³⁸⁰ Moreover, an adjacent mass behind the trachea or main bronchus can produce concavity of the posterior portion of them without invasion (Fig. 34-10) because the cartilage rings are incomplete in the posterior portion of the trachea and main bronchi.¹⁷⁵

According to Picus and coworkers,⁴⁶⁴ aortic invasion can be diagnosed by CT if the area of contact between the esophageal cancer and the aorta creates an arc of more than 90 degrees (Fig. 34-11). The accuracy of this 90-degree criterion is more than 90% when mediastinal fat planes are preserved above and below the tumor.^{36, 464, 576} If the arc is less than 45 degrees, aortic invasion is considered to be absent; an arc of 45 to 90 degrees is considered indeterminate.⁴⁶⁴ The overall accuracy of MRI in evaluating aortic invasion is similar to that of CT.^{175, 459, 563} Although the presence of the fat plane rules out invasion, absence of the fat plane between the aorta and tumor does not always indicate invasion, such as in tracheobronchial invasion.

Figure 34-9. Esophageal cancer with tracheal invasion. CT scan shows circumferential wall thickening of the proximal esophagus (arrowheads), which shows irregular interface with the posterior wall of the trachea (arrows), indicating direct extension into the lumen.

Figure 34-10. Concavity of the posterior tracheal wall mimicking invasion. Although the posterior tracheal wall is concave (arrow), the surface of the posterior wall is smooth. Note that only the concavity of the trachea without surface irregularity or apparent intraluminal protrusion does not suggest the tumor invasion.

This major pitfall occurs in cachectic patients in whom the fat planes are absent throughout the mediastinum. Without clear evidence of displacement of the aorta and direct contact between the aorta and tumor, aortic invasion cannot be diagnosed.³⁸⁰

Figure 34-11. Esophageal cancer with aortic invasion. An arc (curved arrow) of the contact between the esophageal cancer (arrows) and the aorta (arrowheads) is more than 90 degrees, indicating aortic invasion.

Bone invasion can be easily identified on CT or MRI with the findings of bone destruction and replacement of bone by soft tissue that are continuous with the main tumor mass.^{380, 563} Pleural, pericardial, diaphragmatic, and gastric invasion are not contraindications to surgery because the involved areas can be removed together with the tumor mass at the time of operation. Therefore, the misdiagnosis with CT in identifying tumor involvement in these areas is less critical.^{36, 576} Pericardial invasion can be readily diagnosed with high accuracy, ranging from 88% to 97%.^{474, 578}

CT or MRI appearances of pericardial invasion^{474, 563} are as follows:

1. Pericardial thickening adjacent to the tumor.
2. Pericardial effusion.
3. Inward deformity of the heart with loss of the intervening fat plane at the level of the tumor, with intact fat above and below the tumor.

Although the patient may be cachectic or may have undergone radiation, which can obliterate normal fat planes, tumor invasion should be suggested when a localized obliteration of the fat plane is noted with preserved fat planes above and below the lesion.^{222, 417, 580} The CT feature of gastric invasion is a soft tissue mass extending from the esophageal tumor into the proximal stomach under adequate distention.⁴⁶⁴ On MR images, gastric tumor extension is diagnosed when a T2-weighted image depicts a mass of high signal intensity to the gastric wall extending from the esophageal tumor into the gastric fundus.⁵⁶³

The overall accuracy of gastric invasion on CT and MRI ranges from 79% to 97%.^{240, 563} Gastric invasion frequently occurs when the tumor locates in the distal esophagus, especially in adenocarcinoma. Pleural and diaphragmatic invasion cannot be clearly demonstrated on CT^{464, 474} because adhesion to these structures by tumor can easily occur without invasion.

Lymph Node Metastasis

Metastatic spread of esophageal cancer occurs commonly in regional or distant lymph nodes because a rich network of lymphatic channels along the esophagus and lack of serosa allows early extraesophageal tumor invasion.⁵²¹ Cross-sectional images, including endoscopic ultrasonography, CT, and MRI, have shown a wide range of accuracy in detecting lymph node metastasis.^{240, 419, 459} However, most concur that endoscopic ultrasonography shows the highest accuracy (73% to 88%) among them.^{240, 419}

With regard to the accuracy of CT and MRI, one prospective series showed only 56% accuracy for mediastinal lymph nodes and 45% for abdominal lymph nodes.²⁴⁰ Although controversial, MRI may provide accuracy similar to that of CT in detecting a metastatic mediastinal lymph node.³²⁸ It has been widely accepted that lymph nodes with a short axis greater than 1 cm in diameter should be considered to be a metastasized node in the periesophageal region, other mediastinal regions, and the abdomen.⁶⁰⁶ However, this criterion still poses a problem because of the high frequency of false-positive and false-negative results.⁵⁷⁸

In some instances, concomitant presence of inflammation associated with tumor may produce large lymph nodes, which limits the accurate predictions of lymph node metas-

tasis on CT. The size criteria for lymph node metastasis typically used for CT are not applicable to esophageal tumors because of microscopic invasion of normal sized nodes. Application of different size criteria to some lymph node chains may improve the capability of cross-sectional imaging for determining metastatic node; according to Balfe and associates,¹⁶ the upper limit of normal lymph node in gastrohepatic ligament was 8 mm.

Distant Metastasis

The liver (32%) and the lung (21%) are the target organs most frequently affected by esophageal carcinoma metastasis. CT clearly demonstrates the metastatic lesions in solid upper abdominal organs and the lung. On CT scans, pulmonary metastasis is shown as one or multiple nodules, and pleural effusion may coexist. Often a single pulmonary nodule produces the dilemma in predicting metastasis. In this situation, biopsy of the solitary pulmonary nodule is usually recommended. Liver metastasis manifests as single or multiple nodules with variable size and ill-defined margins, which are not enhanced as much as normal parenchyma after administration of an IV contrast agent. Although the frequency is low, central necrosis in the metastatic nodule may mimic hepatic cyst.³⁸⁰

Adrenal gland enlargement may be another pitfall in the evaluation of metastasis. Adrenal enlargement in patients with esophageal cancer does not always indicate metastasis, because adrenal adenoma is the most common cause of adrenal enlargement. Therefore, radiologic differentiation of adrenal metastasis from adenoma is important in the management of patients with esophageal cancer. Findings that lead to radiologic diagnosis of adenoma include a homogeneous mass, a diameter less than 5 cm, and an attenuation value between -5 and 10 Hounsfield units (HU) on CT.²⁷⁹ Compared with adenoma, adrenal metastasis usually shows an enlarged heterogeneous gland with loss of normal adrenal shape.⁶⁰⁶

Resectability, Postoperative Findings, and Recurrence

The actual goal of pretreatment staging in esophageal carcinoma is to evaluate tumor resectability. The major criteria for nonresectability include (1) aortic invasion, (2) tracheal invasion, and (3) distant metastasis. According to Takashima and colleagues,⁵⁶³ sensitivity, specificity, and accuracy for resectability are 100%, 84%, and 87%, respectively, for MRI and 100%, 80%, and 84%, respectively, for CT.

In evaluating patients with esophagogastrectomy, the radiologist must be aware of postoperative appearance. Normal postoperative CT features have been described by Heiken and coworkers.²²⁹ In patients who have undergone a high anastomosis with gastric conduit, both the esophagogastric junction and the stomach are located in the right paravertebral area, and the proximal esophagus above the anastomosis can be dilated (Fig. 34-12). In the lower retrocardiac area, the stomach passes from right to left directly anterior to the descending aorta and then begins to narrow as it enters the diaphragmatic hiatus anterior to the aorta. In patients who have undergone low esophagogastric anastomosis, the esophagogastric junction and the stomach

Figure 34-12. Postoperative status of esophageal cancer (high esophagogastric anastomosis). *A*, Proximal anastomosis (esophagogastric junction) (arrows) is located posterior to the trachea and right to the vertebra. *B*, In the distal portion, the stomach (arrows) passes from right to left in front of the descending aorta.

lie in the left paravertebral region adjacent to the lower thoracic descending aorta.

CT and MRI can play a role in postoperative evaluation because they aid in the diagnosis of early postoperative complications, including mediastinitis or abscess caused by anastomotic leak, lung parenchymal consolidation, pleural effusion or empyema, and subphrenic abscesses.^{200, 229, 515} Among these complications, mediastinitis related with anastomotic leak is fatal. When patients who have undergone esophagectomy present with cervical, thoracic, or epigastric pain, fever, dysphagia, or respiratory distress, complications related to anastomotic leak should be considered.⁵¹⁵

CT findings with postoperative recurrence include soft tissue mass, impression and displacement of normal structures, metastasis to distant organs, abdominal lymph node enlargement, pericardial effusion, and pleural effusion.⁷⁵

Other Malignant Tumors

Small-Cell Carcinoma

Small-cell carcinoma of the esophagus is a rare but aggressive malignant tumor. It occurs in older adults and shows a slight male predominance.⁴⁴ Clinical manifestations include rapidly progressive dysphagia, odynophagia, weight loss, and symptoms and signs related to hormone production from small-cell-like carcinoma of the lung.^{44, 426} It is notorious for its tendency for early metastasis, and

rapid fatal course and is indistinguishable from pulmonary small-cell carcinoma.^{237, 436}

Only a few radiologic features of esophageal small-cell carcinoma have been reported. Barium study reveals a smoothly marginated, polypoid or fungating mass with a relatively flat central ulcer in the midesophagus.³³⁸ Usually the tumor does not narrow the lumen of the esophagus but expands the lumen. On CT, the tumor shows irregular, eccentric esophageal wall thickening and extensive lymph node metastasis to the mediastinum, supraclavicular region, and abdomen (Fig. 34-13).^{147, 586} Because extensive and distant lymph node metastases appear to be a prominent feature of this tumor at presentation, CT examination should cover the abdomen as well as the whole thorax.¹⁴⁷

Malignant Stromal Tumor (Leiomyosarcoma)

Malignant stromal tumor of the esophagus has been recognized as a rare lesion, accounting for fewer than 1% of all esophageal malignant neoplasms. It usually is found in middle-aged or older adults. Because there is no smooth muscle in the esophagus above the aortic arch, a malignant stromal tumor usually occurs in the middle and distal third of the esophagus.⁶⁰⁵ It carries a better prognosis than squamous cell carcinoma owing to its tendency for slow growth, low grade, and late metastasis.^{73, 340, 480} The growth pattern can be classified as *polypoid* or *infiltrating*.

CT features include thickening of the esophageal wall and soft tissue mass containing areas of low attenuation

Figure 34-13. Small cell carcinoma of the esophagus. A, CT scan at the level of aortic arch demonstrates eccentric wall thickening with soft tissue attenuation in the proximal esophagus. The esophageal lumen (arrow) is filled with contrast medium. B, CT scan of the upper abdomen demonstrates multiple enlarged lymph nodes (arrowheads) in the perigastric area.

associated with necrosis, large exophytic components, and extraluminal gas or orally administered contrast material within the tumor (Fig. 34-14).³⁴⁰

In the polypoid type of the lesion, even if the tumor is large, it does not usually cause obstruction. Therefore, a bulky, nonobstructing intraluminal mass with a large exophytic component should be considered a malignant stromal tumor. In contrast, an infiltrating tumor is indistinguishable from infiltrative esophageal cancer.³³³ On MR images, this tumor may show a mass with similar signal intensity, with skeletal muscle on T1-weighted images and higher signal intensity on T2-weighted images. There may be an area of signal void owing to extraluminal gas within the tumor.³⁴⁰

Figure 34-14. Leiomyosarcoma of the esophagus. CT scan shows a large mass (arrowheads) with heterogeneous enhancement. Despite the large size of the tumor, the esophageal lumen (arrow) is merely displaced but not collapsed.

Malignant Spindle Cell Tumor

Malignant spindle cell tumor is an unusual malignant tumor of the esophagus that contains both carcinomatous and sarcomatous elements with spindle cell metaplasia of the carcinomatous portion of the tumor, hence, the name *spindle cell carcinoma*.^{5, 34} On pathologic examination, these tumors consist of innumerable tumor-like spindle cells with islands or nests of carcinomatous cells interspersed throughout the lesion. Affected individuals usually present with recent onset of dysphagia and weight loss. Unfortunately, they carry the same poor prognosis as squamous cell carcinoma of the esophagus.³³⁵

No reports have demonstrated CT features of malignant spindle cell tumor. In our experience, this disease appears as a large intraluminal mass without obstruction. The lesion shows homogeneous soft tissue attenuation similar to that of stromal tumors on CT scans and more intense enhancement than the adjacent esophageal wall on MR images (Fig. 34-15). On esophagography, malignant spindle cell tumor is shown as a giant polypoid intraluminal mass that characteristically expands the esophagus without obstruction.⁴³⁶

The differential diagnosis for these expansile intraluminal masses includes other rare malignant tumors of the esophagus, such as malignant stromal tumor and malignant melanoma.³³⁵

Lymphoma

The incidence of esophageal lymphoma is lowest among all GI tract tumors, accounting for only 1% to 2% of all cases of GI lymphoma.^{53, 435, 511} This tumor usually occurs secondary to generalized non-Hodgkin's lymphoma with direct invasion of the esophagus by lymphomatous nodes in the mediastinum, contiguous spread of lymphoma from the gastric fundus, or synchronous development of lymphoma in the wall of the esophagus.⁵¹¹

In rare instances, primary esophageal lymphoma may occur in patients without extraesophageal disease. Primary

Figure 34-15. Malignant spindle cell tumor of the esophagus. *A*, CT scan shows a giant polypoid intraluminal mass (arrowheads) with homogeneous soft tissue attenuation. This lesion is hypointense on T1-weighted image (*B*) and heterogeneously hyperintense on T2-weighted image (*C*). After administration of gadolinium-DTPA (*D*), the lesion (arrowheads) shows heterogeneous considerable enhancement. The lesion does not cause esophageal obstruction despite its large size.

esophageal lymphomas in patients with acquired immunodeficiency syndrome (AIDS) have been reported.^{479, 519} Most cases of esophageal lymphoma have been discovered at autopsy and in patients with widespread disease because esophageal lymphoma does not usually produce symptoms. Occasionally, esophageal lymphoma may cause dysphagia,

bleeding, and fistulas.^{333, 479, 519} Radiographically, esophageal lymphoma shows irregular narrowing of the distal esophagus owing to contiguous spread of the tumor from the gastric fundus. However, this finding cannot be used to differentiate esophageal lymphoma from carcinoma extending from the gastric fundus to the esophagus.^{76, 80, 135, 333}

On CT, esophageal lymphoma is manifested as irregular thickening of the esophageal wall with or without large ulceration.^{479, 519} In addition, CT is useful in the evaluation of mediastinal involvement of the lymphoma. Although esophageal lymphoma is rare, the diagnosis should be considered in patients at risk for AIDS when the radiologic findings are not typical for infectious esophagitis or Kaposi's sarcoma. Occasionally, these tumors can produce enlarged, tortuous folds, mimicking the appearance of varices. When multiple nodules are present in the esophagus, the differential diagnosis includes leukemic infiltrates, hematogenous metastases, Kaposi's sarcoma, and multiple stromal tumors.⁴⁷⁹

Primary Malignant Melanoma

Primary malignant melanoma of the esophagus is extremely rare. It originates from the small numbers of melanocytes and their precursors in the esophageal mucosa. As in skin melanoma, esophageal melanoma presumably develops because of malignant degeneration of these preexisting melanocytes.^{116, 549} According to Yoo and coworkers,⁶¹³ primary malignant melanomas of the esophagus produce characteristic radiographic findings; tumors appear on barium studies as bulky, polypoid intraluminal masses that focally expanded the esophagus without causing obstruction. They tend to grow intraluminally along the longitudinal axis of the esophagus, which leads to the development of a polypoid mass that widens the lumen as it enlarges.

On CT scans, malignant melanomas are shown as large masses involving the esophagus, which may infrequently be associated with lymphadenopathy. Spindle cell carcinoma of the esophagus is the major consideration in the differential diagnosis of a larger, polypoid intraluminal mass in the esophagus.

Other Diseases

Inflammation

Most inflammations of the esophagus are caused by gastroesophageal reflux or infection. Gastroesophageal reflux disease (GERD) is the most common inflammatory disease involving the esophagus. Esophageal infection occurs frequently in immunosuppressed patients with malignancy, organ transplantation, and AIDS and includes *Candida albicans*, herpes simplex, and CMV.^{380, 428} Candidiasis is the most common cause of infectious esophagitis and is thought to result from downward spread of the fungus from the oropharynx to the esophagus. In patients with AIDS, a deep esophageal ulcer, an intramural dissection, or fistula formation should suggest the diagnosis of esophageal TB.

On CT scans, esophagitis appears as a long-segmental, uniform, circumferential esophageal wall thickening, often combined with a target sign (Fig. 34-16).^{43, 107, 495} According to Berkovich and associates,⁴³ 55% of patients with esophagitis show a thickened esophageal wall more than 5 mm thick and 17% of patients exhibit the target sign. The thickening is caused by edema, infiltration with inflammatory cells, and muscular spasm. Compared with esophageal carcinoma, which usually shows asymmetrical wall thickening and radial extension into the mediastinum, the mediastinal fat plane is preserved in esophagitis.³⁸⁰

Figure 34-16. Esophagitis. CT scan shows circumferential esophageal wall thickening with the "target sign" (arrowheads). The esophageal fat is preserved in esophagitis, which is a point of differentiation from esophageal carcinoma.

Pearlberg and coworkers⁴⁵⁵ described the CT findings of esophageal intramural pseudodiverticulosis, which was associated with long-standing esophagitis and characterized by dilatation of the excretory ducts of esophageal mucous glands. CT features of this condition include intramural air collections at multiple levels within a thick-walled esophagus. Postinflammatory stricture may produce luminal narrowing without wall thickening. When circumferential soft tissue thickening is observed, it is due to fibrosis.³⁸⁰

The esophagus may be involved secondarily from adjacent mediastinal inflammatory processes. Histoplasmosis or TB may result in tracheoesophageal or bronchoesophageal fistula and subsequent aspiration pneumonia or lung abscess. The most common cause of esophageal TB is secondary involvement from adjacent tuberculous lymphadenitis rather than primary esophageal TB. CT is useful in detecting the fistula between the esophagus and mediastinal lymphadenopathy (Fig. 34-17).^{42, 254, 602}

Im and associates²⁵⁴ analyzed five patients with esophagomediastinal fistula caused by tuberculous lymphadenitis and observed amorphous gas collections along the fistulous tract with evidence of enlarged mediastinal lymph nodes. These findings in patients with tuberculous lymphadenitis should suggest the presence of an esophagomediastinal fistula.

Berkmen and Auh⁴² also reported that CT could demonstrate the fistula that appeared as an air-filled communication between the esophagus and airway (Fig. 34-18). Thin section (2 to 4 mm) may be helpful in their detection.

Figure 34-17. Fistula between the esophagus and tuberculous lymphadenopathy. CT scan demonstrates an air-filled fistulous tract (arrows) between the esophagus (arrowheads) and the enlarged subcarinal lymph node (curved arrows).

Even when the actual fistula is not demonstrated, associated findings, including infiltration of mediastinal fat due to inflammation and fibrosis, pulmonary consolidation, pulmonary cavitation, and pleural fluid, help suggest the diagnosis.

Achalasia

Achalasia is an uncommon disease of the esophagus, with an incidence of 0.6 to 0.2 per 100,000 per year.^{48, 478} It is caused by aperistalsis of the lower esophageal segment and by inadequate relaxation of the lower esophageal

Figure 34-18. Tracheoesophageal fistula. CT scan shows an air-filled communication (arrow) between the esophagus (arrowhead) and the mainstem bronchus (curved arrows).

sphincter (LES). Although the pathogenesis of achalasia is obscure, the histologic basis is unknown.⁴⁷⁸ There is no sex predilection. The condition usually occurs in middle-aged patients. Clinical symptoms are usually dysphagia, which is usually worse with liquids than with solids, although sometimes only nonspecific symptoms, such as heartburn, may be present.

The diagnosis of achalasia is usually made on the basis of esophagography, manometry, nuclear examination, and endoscopy. Radiographic findings of achalasia have been reported by many authors.^{134, 359, 444} On barium study, the primary peristalsis is absent on all swallow studies. The lower end of the esophagus shows a smooth "beaklike" tapering located at the level of the esophageal hiatus. This tapering reflects LES dysfunction and failure of the barium bolus to distend the tonically contracted LES.⁴⁴⁴

CT features of achalasia have been described. Rabuschka and colleagues⁴⁷⁸ reported that a unique CT feature of achalasia is moderate dilatation of the esophagus with a mean diameter of 1.4 cm at the carinal level, not combined with wall thickening in the distal segment of the esophagus (Fig. 34-19). They mentioned that normal wall thickness is the most important feature that distinguishes patients with achalasia from those with other esophageal diseases.

The role of CT in the evaluation of patients with achalasia exists not only to detect the disease and its complications but also to demonstrate atypical features that may indicate the presence of other diseases or superimposed benign or malignant processes. Other causes of LES narrowing that may mimic achalasia include intrinsic or extrinsic neoplasms, peptic stricture, and complications of scleroderma. Patients with tumor infiltration into the distal esophagus may report symptoms similar to achalasia. This entity has been named *pseudoachalasia*, and it is important to distinguish it from *primary achalasia*.

Esophageal cancer occurs in 2% to 7% of patients with long-standing achalasia.^{429, 478, 608} In this situation, cancer develops in the midesophagus, and the etiologic mechanism has been presumed to be stasis and irritation of the esophagus.⁴⁷⁸ When patients with achalasia experience rapid worsening of symptoms, the possibility of superimposed esophageal cancer is suggested.

Ott and coworkers,⁴⁴⁵ investigating the relationship between achalasia and hiatal hernia, found that hiatal hernia is inversely related to achalasia; hiatal hernia is uncommon in patients with achalasia compared with the normal population. If patients with achalasia have hiatal hernia, another cause for the dysphagia and abnormal motility should be sought.

Varices

Esophageal varices may be classified as *uphill* or *downhill*; the former category is more common than the latter. Uphill varices develop by portal hypertension, in which increased portal venous pressure leads to hepatofugal venous flow through the coronary vein into a plexus of dilated esophageal and periesophageal veins. Downhill varices develop by obstruction of superior vena cava and result in reversal of flow into vein of the cervical and upper thoracic esophagus via the superior intercostal vein, bronchial vein, inferior thyroid vein, and other mediastinal collateral ves-

Figure 34-19. Achalasia in a 47-year-old woman. *A*, CT scan shows dilated, fluid-filled esophagus (arrow). *B*, In this patient, the distal esophageal wall thickness (arrow) is normal, in contrast with other obstructive causes of the esophagus.

sels.²³⁵ Esophageal varices are important because of the potentially catastrophic consequences of variceal rupture and hemorrhage.

On CT scans, esophageal varices are recognized by the presence of a thickened, lobulated esophageal wall that is markedly enhanced after administration of IV contrast medium. Without such an infusion, the varices are indistinguishable from neoplasms or esophagitis.^{22, 94, 386} Secondary signs in esophageal varices include the presence of hepatic disease, gastric varices, and recanalization of venous structures such as the umbilical vein.⁴²⁸

According to Balthazar and associates,²² CT is superior to barium esophagography in evaluating the presence and extent of periesophageal varices and portal hypertension, although the sensitivities in detection of the lesion are similar. CT features of esophageal varices before and after endoscopic esophageal sclerotherapy include esophageal wall thickening; low attenuation within the wall, giving the esophagus a laminated appearance; a mediastinal effusion of predominantly low attenuation that is often masslike; obliteration of mediastinal fat planes; thickening of the diaphragmatic crura; pleural effusions; and subsegmental atelectasis (Fig. 34-20).³⁸³

On CT scans, therapeutically sclerosed esophageal varices may sometimes mimic esophageal carcinoma.²¹⁹ With the increasing use of sclerotherapy, the radiologist may expect to see an increasing number of nonenhancing esophageal varices on CT.

Trauma

Esophageal Hematoma

Esophageal hematoma is related to variable conditions such as abnormal hemostasis, endoscopic instrumentation,

variceal sclerotherapy, foreign body ingestion, remote trauma, and vomiting.^{120, 238, 619} Clinical manifestations include sudden onset of retrosternal chest pain, dysphagia, and hematemesis. Most esophageal hematomas resolve spontaneously with only conservative treatment and do not result in esophageal perforation.³³⁶

On barium studies, the hematoma appears as an ovoid or elongated submucosal mass in the esophagus. When a mucosal laceration is present (particularly after iatrogenic injury), contrast medium may dissect beneath the mucosa into the hematoma. This intramural dissection may produce a characteristic “double-barreled” appearance owing to parallel collections of contrast medium in both true and false lumina, separated by a thin, radiolucent stripe.^{336, 457} However, intramural tracks can also be caused by Crohn’s disease, *Candida* esophagitis, or tuberculous esophagitis.⁴⁵⁷

On CT scans, esophageal hematoma appears as a nonenhancing submucosal lesion with high attenuation or low attenuation in the middle and lower esophagus.

MRI reveals an intermediate signal intensity on T1-weighted images and a hyperintense signal on T2-weighted images.^{120, 619}

Esophageal Perforation

Esophageal perforation is a catastrophic condition that may rapidly progress to fulminant mediastinitis and septic shock. Most cases are caused by endoscopy or other forms of esophageal instrumentation. In other cases, spontaneous perforation of the esophagus (Boerhaave’s syndrome) may occur as a result of a sudden, rapid increase in intraluminal esophageal pressure.

The initial symptoms and signs include sudden onset of severe retrosternal chest pain, vomiting, and subcutaneous

Figure 34-20. Esophageal and paraesophageal varices. *A*, On this unenhanced CT scan, esophageal wall (arrow) is slightly thickened and nodular lesions (arrowheads) adjacent to the esophageal wall are noted. *B*, After administration of intravenous contrast medium, the esophageal wall (arrow) and multiple nodular lesions (arrowheads) are strongly enhanced.

emphysema with crepitus in the soft tissues of the anterior chest wall (*mediastinal crunch*). In some cases, however, the initial signs and symptoms are nonspecific and may consist of hypotension, sepsis, or fever, falsely suggestive of myocardial infarction, acute aortic dissection, or intra-abdominal abnormalities.^{266, 274, 387, 454, 598} The prognosis is directly related to the interval between perforation and initiation of therapy; within 24 hours, the mortality rate for thoracic esophageal perforation exceeds 80%.¹³

In patients with spontaneous esophageal perforation, chest radiographs may reveal pneumomediastinum associated with left pleural effusion or, less commonly, right pleural effusion or bilateral effusions. Esophagography may demonstrate extravasation of contrast medium from the left lateral wall of the distal esophagus into the adjacent mediastinum. Often, however, the clinical features are atypical, and up to 10% of patients with esophageal perforation may have false-negative findings on contrast esophagography.

CT features of esophageal perforation include esophageal wall thickening, periesophageal fluid, extraluminal air, pleural effusion, and pericardial effusion (Fig. 34-21). Pleural effusions are usually bilateral. CT is ideally suited for defining the extent of extraluminal air-fluid collection and for detecting small amounts of extravasated contrast material not appreciated at esophagography. In addition, CT may also be useful in monitoring the clinical course of patients treated conservatively.^{14, 137, 143, 274, 460}

Foreign Body Impactions

Esophageal foreign body impaction usually occurs in children, who tend to ingest coins, toys, or other foreign materials. In adults, foreign body impaction in the esophagus is usually caused by an inadequately chewed bolus of food or bones. Unchewed food tends to lodge in a lower

esophageal ring or stricture, whereas bones tend to lodge in the pharynx near the cricopharyngeus.³³⁶ Most patients with food impaction present with sudden onset of chest pain, odynophagia, or dysphagia. In contrast, young children usually exhibit respiratory distress, drooling, or regurgitation.⁵⁵⁶

Esophageal perforation is rare, affecting fewer than 1% of all patients with foreign body impaction, but the risk of perforation increases significantly if the impaction persists

Figure 34-21. Esophageal perforation (Boerhaave's syndrome) in a 56-year-old man. After vigorous vomiting, the patient experienced sudden chest pain. CT scan shows a thickened esophageal wall (arrow), pneumomediastinum (asterisk), regurgitated gastric content (white arrows), and pleural effusion (arrowheads).

Figure 34-22. Sliding hernia. The stomach (asterisk) and esophagogastric junction (arrow) are located in the mediastinum. Note that the esophagogastric junction is above the diaphragm, which is a crucial criterion in differentiating sliding hernia from paraesophageal hernia.

longer than 24 hours and if the perforation of the cervical esophagus with a foreign body produces a retropharyngeal

Plain radiography, especially lateral radiographs of the neck, may occasionally demonstrate bones or other radiopaque foreign bodies.

Barium study is another option when a foreign body is suspected in the esophagus; barium can determine whether a foreign body is present and whether it is causing obstruction. The impacted foreign body typically appears as a polypoid filling defect in the esophagus with an irregular

meniscus owing to barium outlining the superior border of the impacted food bolus.

CT is also useful in evaluating esophageal foreign body impaction. With its soft tissue and bone windows, CT may replace the barium swallow because of its superior detection of thin, small, minimally calcified foreign bodies that are often obscured by overlying tissues. CT can also visualize inflammatory changes in the adjacent structures.^{46, 595}

Hiatal Hernia

Hiatal hernia is caused by a weakness or tear of the phrenoesophageal membrane. It can be divided into two types:

1. *Sliding* hernia, in which the gastroesophageal junction is above the esophageal hiatus of the diaphragm.
2. *Paraesophageal* hernia, in which all or portions of the stomach herniate into the chest but the gastroesophageal junction is below the diaphragm (Figs. 34-22 and 34-23).

Approximately 99% of hiatal hernias are sliding, and the remaining 1% are paraesophageal.³³⁶ Although the incidence of paraesophageal hernia is much lower than that of sliding hernia, patients with a paraesophageal hernia have a higher risk for the development of volvulus, incarceration, and strangulation of a herniated portion.

Hiatal hernia can be readily detected on a single barium study, but CT and MRI also can demonstrate the size, content, and orientation of the herniated stomach within the lower thoracic cavity as well as the location of the gastroesophageal junction.^{85, 320, 588}

In some instances, only omental fat can be herniated into the chest while the stomach remains in the abdomen; this is referred to as a *paraesophageal omental hernia*. On CT and MRI, this situation may mimic a mass containing fat in the mediastinum. Characteristic CT and MRI features of paraesophageal omental hernia include a bilobed, retrocardiac fatty mass, with branching blood vessels through-

Figure 34-23. Paraesophageal hernia. The gastric fundus (St) has migrated upward into the mediastinum (A), whereas the esophagogastric junction (arrow) is normally located below the diaphragm (B).

Figure 34-24. Paraesophageal omental hernia. Omental fat (arrows) has herniated into the mediastinum, displacing the esophagus (curved arrow). Note the blood vessels within the lesion (arrowheads), which indicates that the fatty mass is the herniated omental fat.

out, a midline septum, and extension through the diaphragm (Fig. 34-24).^{324, 508}

Diverticula

Diverticula may be classified as *pulsion* and *traction* types. A *pulsion* diverticulum, the most common form, is caused by increased intraluminal pressure related to motility disorders; a *traction* diverticulum is caused by fibrosis in adjacent periesophageal tissues. *Pulsion* diverticula are further classified as a *Zenker's diverticulum* in the proximal esophagus and as an *epiphrenic diverticulum* in the distal esophagus.

Traction diverticula are usually located in the midesophagus.⁵⁵⁶ These diverticula can be readily diagnosed on esophagography. *Pulsion* diverticula show one or more rounded outpouching barium collections from the esophagus (Fig. 34-25), whereas *traction* diverticula are manifested as a tented or triangular-shaped barium collection caused by scarring and retraction by granulomatous disease in adjacent subcarinal or hilar lymph nodes.⁵⁵⁶

Epiphrenic diverticula are typically demonstrated by CT as a thin-walled, air-filled or air-fluid-filled structure communicating with the esophagus (Fig. 34-26). However, those not associated with a distal esophageal obstruction (stricture, achalasia) may remain contracted in a resting state and thus may not be visible. Occasionally, the diverticulum may have to be differentiated from mediastinal abscess or tumors and even hiatus hernia.²⁹⁵

Figure 34-25. Zenker's diverticulum. A, Esophagography demonstrates a barium-filled outpouching lesion from the esophagus. B, CT scan shows air-filled structures (arrows) anterior to the esophagus.

Figure 34-26. Epiphrenic diverticulum. CT scan demonstrates a thin-walled, air-fluid-filled structure (arrows) in the distal esophagus. The esophageal wall (arrowhead) is laterally displaced.

Stomach

Techniques and Normal Anatomy

Optimal luminal distention with either barium, water, or gas is the key for evaluating the gastric wall. In the evaluation of gastric cancer, new protocols using 5-mm incremental or helical scanning, drug-induced hypotonia, prone position, and water-filling methods have been advocated (Fig. 34-27).^{132, 242, 513} Gastric distention is achieved by drinking as much as 1500 mL of water. Peristalsis is minimized by the administration of spasmolytics. This protocol may reduce the limitation of conventional CT caused by beam-hardening artifact, peristalsis, and suboptimal gastric distention.

The normal gastric wall is 2 to 5 mm thick, with 10 mm the upper limit for normal¹⁸⁷; in an air-filled stomach, a 3-mm⁵⁰⁷ or 5-mm¹²¹ wall thickness is considered the

upper normal limit. However, anatomic difficulty is most frequently encountered in the region of the gastroesophageal junction.⁵⁷⁹ As the esophagus becomes an intra-abdominal organ and joins the stomach, it can produce a focal thickening and simulate a mass projecting into the gastric wall. Whenever a soft tissue mass is noted in this region, its relationship to the fissure plane anterior to the caudate lobe should be studied. If the mass and fissure plane are in the same or adjoining sections, a pseudotumor should be suspected. A wall thickness of more than 1 cm is considered abnormal in this region when the stomach is well distended.

In evaluations of the stomach, the most commonly encountered difficulty is the differentiating spurious gastric wall thickening produced by redundant mucosa in an incompletely filled stomach from pathologic thickening. In such instances, additional studies with different patient positioning may be important.

When air techniques are used, the right decubitus position is selected to evaluate the proximal stomach and gastroesophageal junction and the left decubitus position is best to evaluate the distal stomach and duodenum; this is the reversal of the patient's position when a high-density oral contrast agent is used.⁵⁷⁹

When conventional CT is used, the normal gastric wall enhances homogeneously but shows a two-layered or three-layered (multilayered) structure (Fig. 34-28).⁸⁸ The inner layer corresponding to the mucosal layer enhances markedly. The intermediate layer of low attenuation corresponds to the submucosal layer, and the occasionally seen outer layer of slightly higher attenuation corresponds to the muscular-serosal layer. This multilayered mural pattern, however, is difficult to appreciate when the wall measures less than 5 mm thick.²⁴²

The perigastric ligaments contain major vascular structures and lymph nodes, which are important pathways for lymphatic metastasis and direct extension of gastric pathologic processes. The gastrohepatic ligament is located in the most superior portion of the lesser omentum, containing the left gastric artery and coronary vein and lymph nodes. Any rounded structure larger than 8 mm within this ligament should suggest lymphadenopathy or collateral vessels. The gastrosplenic and gastrocolic ligaments con-

Figure 34-27. Prone position with the water-filling method for evaluation of the patient with gastric cancer.

14	At the root of the mesentery (superior mesenteric artery)
15	Along the middle colic artery
16	Para-aortic

tain the gastroepiploic vessels and lymph nodes that drain the greater curvature.

The stomach is supplied by several vessels, including the celiac axis, hepatic artery, and splenic artery. The lymph vessels drain from the following major areas (Table 34-3):

1. Cardia and most of the lesser curvature into left gastric nodes.
2. Pylorus and the distal lesser curvature into the right gastric and hepatic nodes.
3. Proximal portion of the greater curvature into the pancreaticosplenic nodes in the splenic hilum.
4. Distal portion of the greater curvature into the right gastroepiploic nodes in the greater omentum and the pyloric nodes at the head of the pancreas.

Many surgeons prefer to use the lymph node classification system proposed by the Japanese Research Society for Gastric Cancer.²⁶⁵

Malignant Gastric Tumors

Adenocarcinoma

Gastric carcinoma is a worldwide disease. Its incidence varies widely, being higher in Asian than in Western countries. Many factors affect prognosis in patients with gastric cancer, including age, symptoms, tumor size, lymph node involvement, depth of tumor invasion, distant metastasis, histopathologic type, and surgery performed. These tumors may be detected either in an early stage (in which case the mucosa or the submucosa is involved) or in an advanced stage. The gross visual appearance of advanced carcinoma is polypoid, fungating, ulcerated, or infiltrative, whereas that of early carcinoma is either protruded, flat, or depressed.

Vascular structures in patients with gastric cancer have been examined with angiography, microangiography, or both.^{384, 539} In these studies, most gastric cancers showed neovascularity in the arterial and capillary phases and tumor stain in the venous phase of angiography. Neoplastic vessels became more numerous, more tortuous, and wider than normal vessels.³⁸⁴

Tumor Detection

When dynamic CT is performed, gastric cancers show moderate and marked heterogeneous enhancement in the early phase and homogeneous enhancement in the equilibrium phase. In early gastric cancer, CT sensitivity in tumor detection depends on the examination technique as well as on the type and size of the lesion. On conventional CT scans, gastric wall thickening in early cancer appears minimal, usually smaller than 1 cm. Furthermore, a flat or depressed type of early cancer may not be demonstrated by CT. Therefore, the reported sensitivity of CT for early gastric cancer reported may be approximately 50%^{132, 174, 242}; however, use of dynamic helical CT with water ingestion improves the detection of cancer.

The early cancers appear as focal gastric wall thickening with strong enhancement in the most inner (mucosal) layer, especially in the arterial-dominant phase; however, an early gastric lesion smaller than 2 cm in diameter is still difficult to detect on CT.¹³² The presence of a low-attenuation stripe in the middle layer differentiates early from advanced tumors.³¹⁸ Endoscopic three-dimensional (3D) CT, which can provide an overview of the tumor within the lumen of the stomach as seen in gastroscopy, improves the detection rate of early cancer.³¹⁹ However, this technique is time-consuming and is limited in detecting flat or small lesions.

Most advanced gastric adenocarcinomas appear as thickened or abnormally enhancing gastric wall in a localized or circumferential pattern (Fig. 34-29) or intraluminal polypoid mass. Sometimes an ulcer is detected within the thickened area of the gastric wall or within the mass. As a less common variety, there is a *scirrhous* type of gastric carcinoma in which the tumor cells (most commonly, the signet ring cell type) spread predominantly in the submucosa with no or minimal involvement of the mucosal layer (Fig. 34-30). In these cases, CT appears to be more diagnostic than endoscopy or barium study and shows diffuse, circumferential thickening of the gastric wall with a mean thickness of 1.8 cm (range, 1 to 3 cm).²⁸

Because of marked desmoplastic response in mainly submucosal layer of the gastric wall, the thickened wall usually shows homogeneous and prolongs contrast enhancement, especially in the equilibrium phase.²⁸ In contrast with the submucosal layer, the muscularis propria shows edematous thickening in the absence of fibrous connective tissues and thus appears to be hypoattenuated on CT, occasionally causing a target appearance in the thickened gastric wall. Other CT features diagnostic for scirrhous cancer include preservation of a thin rim of hypoattenuated mucosal line, intramural calcifications, and high-grade gastric outlet obstruction.

The differential diagnosis of scirrhous carcinoma includes scirrhous metastases (lung, breast carcinoma); non-Hodgkin's or Hodgkin's lymphoma; and unusual chronic systemic or inflammatory conditions such as sarcoidosis, corrosive gastritis, amyloidosis, and Crohn's disease.²⁸ Calcified gastric carcinomas are rarely reported in the literature, and most of them are caused by mucin-producing adenocarcinoma (Fig. 34-31).²⁵¹ The calcifications in the thickened gastric wall are nodular, miliary, punctate, or homogeneously distributed and are also noted in metastatic lesions, such as lymph nodes and liver.²⁵¹

Figure 34-29. Gastric adenocarcinoma. Early phase (A) of a dynamic CT scan shows mild enhancement of thickened gastric wall (arrow). Scan shows good enhancement in the equilibrium phase (B).

In certain instances of gastric carcinoma, the tumor grows exophytically, thereby simulating a *stromal* tumor (Fig. 34-32). The presence of gastric wall thickening adjacent to an exogastric mass or a gastric outlet obstruction favors gastric cancer, allowing it to be distinguished from gastric stromal tumors.³¹⁷

In contrast with early gastric cancer, the sensitivity of CT in detecting advanced gastric cancer is high (92% to 96%).^{88, 132, 242, 408} However, gastric cancer situated on the horizontally oriented portion of the gastric wall, such as the greater curvature and gastric angle, is difficult to evaluate because of the partial-volume averaging effect.^{88, 242} The use of multiplanar reconstruction (MPR) images following thin-slice thickness (5 mm) helical CT scans aids in the evaluation of these lesions (Fig. 34-33).¹⁷⁴

Tumor Staging

Accurate tumor staging is essential for the appropriate management of patients with gastric cancer. The TNM classification is generally used.

Figure 34-31. Mucinous adenocarcinoma of the stomach. CT scan shows gastric wall thickening (arrows) with poor contrast enhancement and calcifications.

Figure 34-30. Scirrhous adenocarcinoma of the stomach. CT scan shows considerable gastric wall thickening (arrows) with a markedly enhanced submucosal layer and a poorly enhanced thin rim of mucosal layer. Ascites is also seen.

Figure 34-32. Gastric adenocarcinoma with exophytic tumor growth. CT scan shows a heterogeneous mass (M) in the left upper quadrant, simulating an exophytically growing malignant gastrointestinal stromal tumor. Enlarged perigastric lymph nodes (arrows) are seen along the lesser curvature of the stomach.

Figure 34-33. Three-dimensional spiral CT image of advanced ulcerofungating gastric cancer (arrows).

T Category

The T category (tumor invasion) includes the following:

- T0 (no tumor invasion)
- T1 (lamina propria or submucosal invasion)
- T2 (muscularis or subserosal invasion)
- T3 (extraserosal invasion)
- T4 (invasion of adjacent organs)

Although initial reports were encouraging, the efficacy of CT in T staging of gastric cancer has been controversial, and an overall accuracy of 42% to 82% has been reported.^{132, 174, 513}

Some series have also stressed the importance of water filling (>400 mL), study with prone position, and gastric hypotonia to reduce peristalsis and beam-hardening artifacts and suboptimal gastric distention during CT for the evaluation of patients with gastric cancer.^{132, 174, 513} However, use of such optimal techniques along with the introduction of helical CT scan does not appear to improve T staging significantly.¹³²

The prognosis in surgically treated patients with gastric cancer is significantly affected by the presence or absence of intraperitoneal free cancer cells at the time of gastrectomy. According to a series by Kaibara and colleagues,²⁷⁵ who analyzed the relationship between the spatial extent of invasion of the gastric serosa and their 5-year survival rate, intraperitoneal free cancer cells were detected by lavage of the Douglas cavity in 135 (44%) of 309 patients with gross evidence of serosal invasion. Their study also showed that the 5-year survival rate was worsening in patients with wider areas of serosal invasion.

Therefore, the primary role of CT in patients with a known history of gastric cancer is to assess the extragastric tumor extension (Fig. 34-34). The accuracy of CT for predicting serosal invasion ranges between 60% and 83%.^{88, 132, 174} In most series,^{88, 132, 174} understaging was more common than overstaging, probably as a result of CT's limited ability to detect microscopic invasion.

Figure 34-34. Gastric cancer with serosal invasion. CT scan shows circumferential gastric wall thickening (asterisk) with perigastric tumor infiltration (arrowheads).

N Category

Besides depth of invasion, extent of node metastases is one of the most important prognostic factors in gastric cancer without distant metastases.³⁷⁹ Therefore, preoperative evaluation of nodal involvement is essential.

The N category (regional lymph node involvement) includes the following:

- N0 (no involvement)
- N1 (perigastric lymph node metastasis within 3 cm of the edge of the primary tumor)
- N2 (metastasis in perigastric lymph nodes more than 3 cm from the edge of the primary tumor or in lymph nodes along the left gastric, common hepatic, splenic, or celiac arteries)

Compared with conventional CT, helical CT improves the detection of lymph nodes.¹⁷³ However, lymph nodes smaller than 5 mm in diameter cannot be accurately detected by available imaging techniques.^{88, 173} Furthermore, lymph nodes situated in a small space and surrounded by soft tissue, such as the porta hepatis, may be difficult to detect by CT. Discrimination between benign and malignant nodes is usually difficult. However, in a study by Fukuya and coworkers,¹⁷³ hyperattenuation was more common in metastatic nodes, and low attenuation was more common in tumor-free nodes on the early phase of dynamic or helical CT scans.^{88, 173}

Metastatic nodes tended to have larger short-to-long axis ratios (>0.7).¹⁷³ Until recently, CT diagnosis of lymph node metastasis had been based on size criteria. Most studies of GI tract tumors consider lymph nodes 10 mm or larger to have been infiltrated by metastases of solid tumors.^{88, 173} According to this criterion, the sensitivity of CT in nodal staging of gastric cancer has been reported to be variable (range, 48% to 91%).^{52, 88, 560} Understaging is the main drawback of CT because only lymph nodes with a diameter larger than 5 mm are visible and metastases in smaller nodes cannot be detected. Furthermore, the results of two reports^{132, 415} appear to be pessimistic with regard to the nodal staging of CT.

In a study by Mönig and associates,⁴¹⁵ who analyzed

regional lymph nodes from 31 gastrectomy specimens of patients with gastric cancer, 55% of the metastatic lymph nodes were 5 mm or smaller in diameter and 80% of tumor-free lymph nodes were smaller than 5 mm in diameter. In another study by Dux and colleagues,¹³² most metastatic lymph nodes were between 2 and 10 mm in diameter, and helical CT depicted 74% of histologic N0 stages, 45% of N1 stages, and only 32% of N2 stages. Therefore, it may be true that lymph node size is not a reliable indicator for lymph node metastasis; accordingly, CT is not an effective modality for N staging of gastric cancer.

Tumor Spread

The major methods of spread of cancer are by local invasion through contiguity and tissue planes, by the lymphatic system, by the vascular system, and by implantation.⁹⁵ Thus, gastric cancer spreads to the liver, lymph nodes, pancreas, duodenum, transverse mesocolon, peritoneal cavity, and ovary.

In clinical practice, one of the major questions of the surgeon for patients with gastric cancer who do not appear to have distant metastasis, according to CT, is whether there is pancreatic invasion because its presence precludes curative surgery. On CT, pancreatic invasion is suggested when the low-attenuation band of fat between the tumor and the pancreas is absent (Fig. 34–35) or when the gastric tumor abuts the pancreas. When this criterion was applied, the sensitivity of CT in detecting pancreatic invasion was poor (27%) in a series by Sussman and coworkers⁵⁶⁰; in this series, eight patients with intact fat planes had extension into the pancreas and five of another eight patients who were presumed to have pancreatic invasion on CT were eventually shown to have no tumor invasion.

According to a series by Cook and associates,⁹⁸ a sensitivity of 60% was reported. Furthermore, coexisting acute or chronic pancreatitis or associated inflammatory response also causes obliteration of the peripancreatic fat plane.¹¹⁹ Therefore, application of this finding alone seems to have

Figure 34–36. Intramural duodenal spread from gastric cancer. CT scan shows a large polypoid mass (m) in the stomach extending into the second portion of the duodenum (D).

a significant limitation in determining the pancreatic invasion, and more strict criteria may be required.

The diagnostic value of the CT criterion of obliterated fat plane is increased when it is associated with prominent strandings in the perigastric fat plane as well as irregularity along the outer border of gastric wall involved by the tumor. Although additional studies with patients in a decubitus position are time-consuming, they may be helpful in determining focal or diffuse fixation between the pancreas and the stomach.

In certain instances, gastric cancer spreads into the duodenum through the pyloric canal (Fig. 34–36). The incidence varies greatly in surgical and postmortem series (range, 9% to 69%).²⁷⁶ However, the incidence of radiographically detectable transpyloric spread has been reported as only 5% to 25%.⁸⁹ Such spread occurs by direct infiltration through the submucosa or subserosa or by lymphatic transport through the submucosal layer.²⁷⁶ The 5-year sur-

Figure 34–35. Gastric cancer with pancreatic invasion. A, CT scan shows obliterated interface (arrow) between the tumor in the stomach and pancreas along with linear strands. Enlarged perigastric nodes are also seen. B, Axial T1-weighted MR image at a lower level shows obliteration of the fat plane between the enlarged perigastric node and the uncinate process of the pancreas along with diffuse stranding. (From Sohn KM, Lee JM, Lee SY, et al: Comparing MR imaging and CT in the staging of gastric carcinoma. *AJR Am J Roentgenol* 174:1551–1557, 2000.)

Figure 34-37. Hepatoid type of gastric adenocarcinoma. *A*, CT scan shows concentric gastric wall thickening (M) involving the antrum of the stomach. *B*, CT scan at a higher level shows a portal vein thrombus (P) and a metastatic lesion (asterisk) in the caudate lobe of the liver.

vival rate in these patients is poor compared with patients whose tumor is confined to the antrum.²⁷⁶

Rarely, portal venous thrombosis occurs in approximately 0.95% of patients with gastric cancer.²⁵⁷ The thrombosis develops as a consequence of splenic vein involvement by the gastric tumor, and a high incidence of liver metastasis is reported in these patients.²⁵⁷

Hepatoid adenocarcinoma, an adenocarcinoma originating primarily from the gastric mucosa and containing wide and distinctive foci of hepatocellular differentiation, tends to invade portal or hepatic veins and to metastasize to the liver; the prognosis is poor (Fig. 34-37).²⁵⁸ This tumor usually produces a large amount of serum alpha-fetoprotein, as high as the level released by hepatocellular cell carcinoma,²⁵⁸ although one report showed that not all alpha-fetoprotein-producing adenocarcinomas have hepatoid features.⁴²²

Magnetic Resonance Imaging Staging of Gastric Adenocarcinoma

Until recently, MRI had not been popular for staging gastric cancer. The main drawbacks of MRI were its high cost and its lack of effectiveness in comparison with CT. However, the recent development of fast MRI techniques allows an examination during breath-holding for several seconds, thus providing high-quality images of the stomach (see Fig. 34-35). With the use of spoiled gradient-recalled acquisition in the steady state (GRASS) and the water-filling method, Matsushita and coworkers,³⁸² who analyzed 48 patients with gastric cancer, reported an overall accuracy rate of 88% in predicting serosal invasion by observing the changes in a low-signal-intensity band surrounding the gastric lesion.

A later article by Sohn and associates,⁵⁵⁰ who compared CT with MRI for 30 patients with gastric cancer, showed that MRI was comparable with helical CT in T and N staging; the accuracies of MRI and CT were 73.3% and 66.7% for T staging and 55% and 58.6% for N staging, respectively. Although further investigation is necessary, MRI appears to be an alternative modality of choice for tumor staging in patients with gastric cancer.

Local Recurrence of Gastric Adenocarcinoma

Local recurrence of gastric carcinoma after surgery is defined as histologic evidence of a tumor in the surrounding tissues of the resected stomach (i.e., the gastric remnant, the esophageal anastomosis, the pancreas, the duodenal stump, the hepatic pedicle, the splenic hilum, the celiac axis area, and the abdominal wound).⁴⁵⁰ According to autopsy studies, 80% of the patients who underwent gastrectomy for gastric cancer eventually experienced local recurrence with or without distant metastasis.³⁹¹ However, only 19% of all patients with recurrence had resectable lesions on re-exploration; almost 50% of stump recurrences were resectable, whereas only 2 of 34 patients with recurrence at an extragastric site had resectable lesions.⁴⁵⁰

Tumor recurrence at the gastric remnant may occur more commonly in patients with early-stage gastric cancers^{450, 451} very late after surgery.²⁵⁹ Also, the gastric cancers arising in the cardia were prone to anastomotic recurrence.⁴⁵¹ Because barium studies are associated with difficulty in their capability to fully assess the areas mentioned earlier, CT plays an important role in determining the extent of local tumor recurrence or distal metastasis. On CT, recurrence at gastric stump or anastomosis appears as a localized wall thickening or mass (Figs. 34-38 and 34-39). Afferent loop syndrome may be caused by development of the recurrent tumor near the orifice of the afferent loop (Fig. 34-40). However, potential sources of erroneous interpretation include improperly opacified bowel loop, food, surgical plication, gastritis, and gastritis cystica polyposa.²⁰⁷

The most frequently involved lymph nodes are those along the common hepatic artery, the celiac axis, and the hepatoduodenal ligament.²⁰⁷ The presence of lymphadenopathy along the hepatoduodenal ligament may cause moderate to severe biliary tract obstruction. When the pancreas is involved, CT features are indistinguishable from those of primary pancreatic tumor, and enlarged peripancreatic lymph nodes can mimic tumor recurrence in the pancreas.

Most tumor recurrences at the abdominal incision are caused by iatrogenic dissemination of cancer cells during surgery (Fig. 34-41).⁹⁵ However, postoperative fibrosis,

hematoma, abscess, or granuloma cannot be differentiated from tumor recurrence at this site by imaging findings alone. Because tumor recurrences were most common within 2 years after surgery, follow-up CT scanning in a short interval is required at this period for early diagnosis.

Lymphoma

The stomach is the most frequent site of lymphomatous involvement of the GI tract. *Non-Hodgkin's lymphoma* accounts for approximately 80% of cases. Gastric involvement may be isolated but more commonly is part of a generalized disease process.⁵³ Among various prognostic factors that include gender, age, size and location of tumor, histologic type, depth of invasion, and nodal status, depth
